Preface to the Second Edition

A plethora of literature has been published in the field of pediatrics during the past few decades. In the last five years there has been a many folds increase in the knowledge. With each passing moment our knowledge-base, has expanded dramatically, with the resultant emergence of various super- and subspecialties. We, in this edition of *Advances in Pediatrics*, have tried to add the latest management protocols for various diseases. There are some articles which cannot be found in any textbook but are invaluable for the pediatrician who is fresh in practice. The book will also be of great help to a postgraduate appearing in the examination as it gives consolidate information on a number of topics. The efforts put in by us in the past few months have resulted in a unique collation of expertise, clinical application and incisive opinions on the latest in our fields. It has been our pleasure to have a host of eminent academicians and practitioners, both international and national, as a part of this endeavor, each lending their imprint into the development of a thorough and comprehensive compendium. We, in India, are still struggling with abysmal health indices and they are a matter of shame. With the economic upturn, we need to see that the benefits of this percolate down to the poorest of the poor. We have a huge human resource of health care professionals but they are concentrated in the cities. The facility for updating the knowledge are not very good. We hope that the book will go a long way in bridging the gap for updating the knowledge of pediatricians. We are happy that the organizing committee of the PEDICON 2012 have decided that it is very important to disseminate knowledge and towards this end, they are giving a copy of the book to each and every delegate attending the conference. The need of the hour is to be well prepared to meet the adversities that come our way as professionals. Whether we are good, better or the best, we should never let it rest, until our good is better, and our better, the best. That has been the philosophy of our book, and that is the spirit that we would encourage to inculcate in all our readers. A beginning has been made and to see a generation benefit from this vast resource would be most gratifying for us.

Anupam Sachdeva

AK Dutta

Preface to the First Edition

A plethora of literature has been published in the field of Pediatrics during the past few decades. With each passing moment our knowledge base has expanded dramatically, with the resultant emergence of various super and sub specialties. The very notion that a practicing pediatrician, and for that matter even a post graduate student, must be competent to deliver holistic care for the child patient at every juncture and in each of these ramifications of pediatrics, is a challenging prospect and highlights the need for continuing education and enhancement of one's skills. To meet these needs, we considered tracking the current trends of pediatric practice in the form of a concise book. The labors of the past few months have resulted in a unique collation of expertise, clinical application and incisive opinions on the latest in our fields. It has been our pleasure to have a host of eminent academicians and practitioners, both international and national, as a part of this endeavor, each lending their imprint into the development of a thorough and comprehensive compendium. The issues that we have addressed through "Advances in Pediatrics" reflect the health afflictions of the Indian child specifically, both urban as well as rural. Our nation suffers from perhaps one of the highest infant - and under five - mortality rates across the globe, reflecting the non availability and delivery of the neonatal health care system. In such a scenario, the importance of neonatal care assumes principal significance. In the same breath, infectious diseases are perhaps a major cause for mortality too and their management and prevention with appropriate vaccination have been the focus of attention. Our purview extends to include gastroenterology, hemato-oncology, nephrology, pediatric cardiology, emergency and respiratory diseases and neurology amongst others. The need of the hour is to be well prepared to meet the adversities that come our way as professionals. Whether we are good, better or the best, we should never let it rest, until our good is better, and our better, the best. That has been the philosophy of our book, and that is the spirit that we would encourage to inculcate in all our readers. A beginning has been made and to see a generation benefit from this vast resource would be most gratifying for us.

I shall be telling this with a sigh
Somewhere ages and ages hence:
Two roads diverged in a wood, and I—
I took the one less travelled by,
And that has made all the difference.

AK Dutta
Anupam Sachdeva

CHAPTER 1

Setting Up of Neonatal Intensive Care Unit

Ashish Mehta

Setting up an neonatal intensive care unit (NICU) is a challenging job which requires a lot planning and contemplation on many fronts.

A well organized neonatal unit is the back-bone on which clinicians and nurses work to produce the desired outcome. Without a well organized unit, medical and paramedical staff may struggle to apply their skills in a timely and efficient manner, which ultimately affects over-all outcome of the unit. Setting up a good NICU is not a single-handed job, it is a team work. While designing, a lot needs to be planned before putting into practice. Experts with knowledge and skills—like architects, civil and electrical engineers, fire-personnel, interior designers, bio-medical engineers - form a core team. This team works and designs a plan based on requirements of clinicians, nurses and supporting staff.

In a developed country recommended standards of newborn ICU are already made and they are revised at regular intervals. Unfortunately we do not have such standards. National Neonatal Forum has already specified requirements to establish various levels of care in NICU but guidelines to design such units in our country are not there.

Recommended standards of materials, meant suitable for environment of developed country and usage may not be suitable/required for our NICU. One may need to spend a lot to procure such materials. In that case, we need to look at what is best available in our country. Materials that are harmless and durable should be used.

Thus before embarking upon the design of an NICU, following requirements need to be kept in mind:

- Available space for NICU (carpet area)
- Number of beds required (current and future)
- Number of staff required: clinical, personnel in each shift to handle babies and other services.
- Equipment: movable and non-movable
- Light source: emergency and regular

- Acoustic effect: internal and external
- Heating, ventilation system and air conditioning (HVAC).

Once this is decided, following can be planned:

- Space planning: visualized 3D space
- Operational planning-traffic pattern
- Functional location of beds and equipment
- Ancillary services location
- Interior planning
- Surface – floor, walls and ceiling material planning
- HVAC - designing outlets.

Based on the above, a blue-print is prepared. Inputs are required at every level before execution of the design.

NICU LOCATION WITHIN THE HOSPITAL

Ideally, NICU should be in close proximity to the birthing unit in the hospital. If that is not possible, an elevator just adjacent to birthing unit with facility for key operation is desirable. Traffic for other services/disciplines should not pass through NICU. Those NICUs where babies are received from outside, NICU should have direct access to hospital transport receiving area.

Space Requirement

Depending upon the complexity of care rendered, bed space can be planned-Keeping in mind family's involvement in care of an infant.

Traditional design of NICU is of “multiple bed NICU”, where a single big area is designed with multiple beds. Current and more popular concept in developed world is of “single family room NICU”, where mother stays with baby in NICU. Such units not only require huge space, but also more staff. Evidence supports that such designs are practical, popular and justified by increasing awareness of the impact of the sensory environment on premature and ill newborns.

In resource limited set ups such concept may not be viable. In that case, a well spaced multiple bed NICU also serves equal purpose. For level 3 multiple bed NICU, infant bed space should be 120 sqft of unobstructed space. The distance between two baby beds should be 8-12 feet, so that the area adjacent to each infant space will have a minimum width of 4 feet. Each infant space should be designed to allow privacy for infant and family.

Infant space for intensive care infant beds situated in a single infant room should be at least 150 sq.ft per infant to provide adequate space for both equipment and family. The width of aisle in multiple bedroom should be enough to allow for easy movement of all equipment which might be brought to the infant's bedside, as well as for easy access of maternal bed. Aisle width of 8 feet is good enough for this purpose.

FAMILY SUPPORT AREA

Adequate space is required immediately adjacent to the NICU for families. The family hold area should have space for gowns, hand washing, secured storage for their belongings, a small pantry and toilet. The sitting should be comfortable and play area with entertainment material for children should be provided. These rooms should have emergency call and telephone or intercom linkage with NICU staff. It is a good idea to provide internet and education material in this area.

STAFF SUPPORT AREA

Adequate space should be provided within the NICU to meet the professional, personal and administrative needs of the staff. These areas include lockers, lounges, counseling space, education and conference space. On call rooms with adequate facilities are required for relaxation.

MOTHER'S ROOM

A mother's room is an important part of any well-designed NICU. These rooms should be within or immediately adjacent to the NICU. These rooms should be sufficient equipped and sized to accommodate parents and people from various disciplines (clinicians, nurses, social workers, etc.) who may need to meet the parents in private. The aim of these rooms is to encourage over-night stay by parents of the infants in NICU when opportunities arise to do so. The number of rooms will depend on number of growing babies in the NICU, and regional practices. These rooms need to have medical gas and suction outlets. Light music and TV facilities along with educational video/ material are desirable.

SUPPORT SPACE FOR ANCILLARY SERVICES

Specialized feeding preparation area or room should be provided in the NICU, which is away from the bedside.

This area will require hands-free hand washing station, counter for work space, and storage area for formula. A dedicated fridge is required for refrigerated and frozen breast milk.

Other ancillary services such as respiratory therapy, laboratory, pharmacy, radiology, developmental therapy are part of NICU. Distance, size and access are to be decided based on overall working pattern of the hospital, e.g. for multispecialty hospital, all these services can be centralized.

ADMINISTRATIVE SPACE

The disciplines that provide services to the unit, on a daily basis need distinct areas to carry out their responsibilities. Such disciplines can share a single room.

GENERAL SUPPORT SPACE

Adequate facilities should be provided for clean, soiled utilities, medical equipment storage and unit management services.

Clean utility areas are for storage of supplies frequently used in newborn care. Soiled utility room is essential for storing used and contaminated material before its removal from care area. It is desirable to have hand washing facility and covered waste receptacle with foot control. This area should have negative air pressure with 100% air exhausted to the outside. More important would be its location in the NICU. It should be located in such a way that soiled material can be removed without passing from infant care area.

Adequate charting space in form of separate area or desk for tasks like complying detailed records, completing requisitions and telephone communication should be provided.

Ideally three zone storage system is desirable. The first storage area should be control supply of the hospital. Second storage zone is the clean utility area. Third storage zone is for items frequently used at the infant's bedside (in the form of bedside cabinets). While designing third storage zone and charting area, ease of access to the staff, infection and noise control should be considered.

For laundry facility, separate laundry room with washing machine and dryer is required. Commercial grade washer, dryer should be installed.

ISOLATION ROOM

An air-borne infection isolation room is a part any good NICU. This room should have negative air pressure with 100% air exhausted to the outside. Adequate hands free hand washing station, area for gowning and a separate area for clean and soiled material is required near the entrance of the room. At least a single occupancy isolation room should be available for infant suspected with

air-borne infection. A space within the NICU should also be available to safely isolate infants infected with common air borne pathogen. Isolation room should have self closing devices on exit doors.

HAND WASHING STATIONS

Hand washing station should be no closer than 3 feet from an infant bed or clean supply store. NICU where a single infant concept is used, a hands free hand washing station shall be provided with each infant room. In multiple bed room NICU, every infant bed shall be within 20 ft of a hands-free hand washing station.

The sink should be large enough to control splashing and should be designed to avoid standing or retained water. The minimum dimensions for hand washing sink are 24 inches wide × 16 inches front to back × 10 inches deep from bottom of the sink to the top of its rim (61 cm × 41 cm × 25 cm). Hand washing instruction in written and pictorial should be provided above the sinks. There should be no aerator on the faucet.

Sink location, construction material and related hardware should be chosen with durability, ease of operation, ease of cleaning and noise control in mind.

ELECTRICAL GAS SUPPLY AND MECHANICAL NEED

Electrical and gas outlets near each infant bed should be organized, to ensure safety, easy access and maintenance. From available resources in the market, a system should be chosen which can include race ways for electrical conduit and gas piping. There should be minimum 18 to 20 simultaneously accessible electrical outlets.

Minimum number of gas outlets is 3 for air, 3 for oxygen and 2 for vacuum. A provision should be made to allow data transmission to a remote location.

GENERAL LIGHTING

Illumination plays an important role in the healing environment and inappropriate lighting can have negative effect on the health of sick babies. On one side perception of skin tone is critical in NICU, and on the other side continuous exposure to bright light in preterm infants can cause harmful effects.

Ambient lighting levels in infant space should be adjustable through a range of at least 10 to 600 lux as measured at each bedside. Both natural and electrical light sources should have controls that allow immediate darkening of any bed position, sufficient for trans-illumination when necessary. A master switch is desirable when rapid darkening of the room is required. Control of lights should be accessible to staff and families. No direct view of electrical light or sun in infant space should be provided. So as to avoid any infant's direct line of sight to the fixture.

To perform the procedures, separate lighting capable of providing no less than 2000 lux is required. This lighting should be adjustable to the required level when required. Lighting fixtures should be easily cleanable.

In the NICU which has lot of natural light, the issue of fluctuation in ambient temperature should be addressed. The thermal effect can cause fluctuation in ambient temperature. The window glass should be double glazed units with appropriate U-factors and solar factors.

At least one source of daylight should be visible from infant care area. Such windows should also be of double glazed glass and should be situated at least 2 feet from any part of the infant bed to minimize radiant heat loss.

FLOOR SPACE

Floor surfaces should be easily cleanable and should minimize growth of microorganisms. Floors should be highly durable to withstand frequent cleaning and heavy traffic. Consideration should also be given to glossiness, their acoustical properties and density of the material used. Polyvinyl chloride or vinyl is common in flooring materials. The production of PVC generates Dioxin, a potent carcinogen. Dioxin releases are not associated with materials such as polyolefin, rubber (latex) or linoleum. Resilient sheet flooring (medical grade rubber or linoleum) is suitable flooring. While laying the flooring, seams should be heat or chemically welded. Careful carpeting should provide impermeable backing.

WALL SURFACES

As with floors, the ease of cleaning, durability and acoustic properties of wall surfaces must be considered. The outer surfaces of walls must be created with materials that have antibacterial solid mineral surface and should be bacteriostatic.

CEILING FINISHES

False ceilings should be modular type and ideally hermetically sealed. Suspended ceiling should be structured by means of nontoxic silicon application for cleaned rooms, such that an air-tight environment is created in NICU.

AMBIENT TEMPERATURE AND THE VENTILATION

The air temperature of the NICU should be 20 to 26°C (72 to 78°F) and a relative humidity of 30 to 60%.

A minimum of six air changes per hour is required with a minimum of two changes being outside air. Ventilation air delivered to the NICU should be filtered with at least 3 micron HEPA filters. Filters should be located outside the infant care area so that they can be changed easily and safely.

ACOUSTIC ENVIRONMENT

The permissible noise criteria of an hourly L_{eq} is of 45 dB and an hourly L_{10} is of 50 dB. Transient sound should not cross 65 dB. To achieve these conditions, the noise criteria for surroundings should be considered.

Apart from engineering requirements, to run NICU at distinctive level, requires addressing lot many other issues like:

- Protocol based management
- Training of medical and paramedical staff
- Software specifically designed for NICU
- Follow-up clinics

- Maintenance services for medical and nonmedical gadgets.

CHAPTER 2

Neonatal Resuscitation Programme 2010: Changes and the Way Beyond

Vikram Datta

INTRODUCTION

Of the nearly 100 million babies born annually worldwide majority of newborns do not require any assistance for transition from intrauterine to extrauterine life, however 10 percent newborns require intervention while <1 percent require extensive resuscitation.^{1,2}

This article will review the current practices, new recommendations' and special considerations in neonatal resuscitation.

Over the years there have been constant changes in Neonatal Resuscitation Programme (NRP) based on the currently available evidence. The International Liaison Committee on Resuscitation (ILCOR) was formed in 1992 and comprises the eight international resuscitation organizations: American Heart Association (AHA), European Resuscitation Council (ERC), Heart and Stroke Foundation Canada (HSFC), Resuscitation Council of Asia (RCA), Resuscitation Council of Southern Africa (RCSA), Australia and New Zealand Council on Resuscitation (ANZCOR), Inter American Heart Foundation (IAHF).

ILCOR provides a mechanism by which the international science and knowledge relevant to cardiopulmonary resuscitation and emergency cardiovascular care is identified and reviewed and periodically develop and publish a consensus on resuscitation science. ILCOR uses a formal evidence evaluation process to identify and prioritize questions and assign reviewers.

The task of evaluating published research is daunting and to make the process easier, several scientists have outlined categories of evidence and stratified them.

The levels of evidence outline by Sackett and his colleagues in 2000 are as follows:

- 1A = Systematic review of randomized controlled trials (RCTs)
- 1B = RCTs with narrow confidence interval

- 1C = All or none case series
- 2A = Systematic review cohort studies
- 2B = Cohort study/low quality RCT
- 2C = Outcomes research
- 3A = Systematic review of case-controlled studies
- 3B = Case-controlled study
- 4 = Case series, poor cohort case controlled
- 5 = Expert opinion.

Hadorn and his colleagues outlined another way of classifying categories of evidence:

- *Level A:* Well-conducted RCT with 100 patients or more (including multicenter and meta-analyses); well-conducted RCT with fewer than 100 patients (one or institutions and meta-analysis; well-conducted study).
- *Level B:* Well-conducted case-control study, poorly controlled or uncontrolled (including RCT with one or more major or three or more minor methodological flaws), observations studies with high potential for bias, case series or case reports, conflicting evidence with more support.
- *Level C:* Expert opinion

Since publication of the 2005 *International Consensus on CPR and ECC Science With Treatment Recommendations*,³⁻⁵ several controversial neonatal resuscitation issues have been identified. The literature was researched and a consensus was reached on the assessment of oxygenation and role of supplementary oxygen, peripartum management of meconium, ventilation strategies, devices to confirm placement of an advanced airway (e.g. tracheal tube or laryngeal mask airway), medications, maintenance of body temperature, postresuscitation management, and considerations for withholding and discontinuing resuscitation.

International Consensus on Cardiopulmonary Resuscitation and Emergency Cardiovascular Care Science with Treatment Recommendations: 2010

- Newborns born at term actively crying with good tone should not be separated from the mothers, should be put on the mothers chest to dry and to warm.
- All others need to be assessed to determine their need for one or more of the following actions in sequence
 - A. Initial steps in stabilization (dry and provide warmth, position, assess the airway, stimulate to breathe).
 - B. Ventilation.
 - C. Chest compressions.
 - D. Medications or volume expansion.

Each step should be completed in 30 sec, the successful completion of the first step permits progression to the next and is initially based on simultaneous assessment of 2 vital characteristics: heart rate and respirations.

Major Changes in 2010 and Rationale

1. Progression to the next step following the initial evaluation is now defined by the simultaneous assessment of 2 vital characteristics: heart rate and respirations.
2. Oximetry should be used for evaluation of oxygenation because assessment of color is unreliable.
Class I, Level of Evidence B.
3. For babies born at term it is best to begin resuscitation with air rather than 100 percent oxygen.
Level of Evidence B, Class II B.
4. Administration of supplementary oxygen should be regulated by blending oxygen and air should regulate administration of supplementary oxygen, and the concentration delivered should be guided by oximetry.
Class IIb, Level of Evidence C.
5. The available evidence does not support or refute the routine endotracheal suctioning of infants born through meconium-stained amniotic fluid, even when the newborn is depressed.
Class IIb, Level of Evidence C.
6. The chest compression-ventilation ratio should remain at 3:1 for neonates unless the arrest is known to be of cardiac etiology, in which case a higher ratio of 15:2 should be considered.
Class IIb, Level of Evidence C.
7. Therapeutic hypothermia should be considered for infants born at term or near-term with evolving moderate to severe hypoxic-ischemic encephalopathy, with protocol and follow-up coordinated through a regional perinatal system.
Class IIa, Level of Evidence A.
8. Cord clamping should be delayed for at least 1 minute in assessments, auscultation of the heart is the most accurate, babies who do not require resuscitation. Evidence is insufficient to recommend a time for clamping in those who require resuscitation.
Level of Evidence 1.

9. It is appropriate to consider discontinuing resuscitation if there has been no detectable heart rate for 10 minutes. Many factors contribute to the decision to continue beyond 10 minutes.
Class IIb.

Rationale

1. Heart rate should remain the primary vital sign by which to judge the need for and efficacy of resuscitation. Auscultation of the precordium should remain the primary means of assessing heart rate. There is a high likelihood of underestimating heart rate with palpation of the umbilical pulse, but this is preferable to other palpation locations.⁵⁻⁷
2. For babies who require ongoing resuscitation or respiratory support or both, the goal should be to use pulse oximetry as color is a poor indicator of oxygenation and both hypoxia and hyperoxia are detrimental. The sensor should be placed on the baby's right hand or wrist before connecting the probe to the instrument.⁸
3. In term babies 100 percent oxygen conferred no advantage over air in the short-term and resulted in increased time to first breath or cry or both.^{9,10}
4. Because many preterm babies of 32 weeks' gestation will not reach target saturations in air, blended oxygen and air may be given judiciously and ideally guided by pulse oximetry. Both hyperoxemia and hypoxemia should be avoided. If a blend of oxygen and air is not available, resuscitation should be initiated with air.¹¹
5. In healthy neonates suctioning of the mouth and nose can cause cardiorespiratory complications. In infants who are intubated, sedated, or paralyzed following resuscitation, endotracheal suctioning in the absence of secretions may result in a decrease in oxygenation, an increase in cerebral blood flow and intracranial pressure, and a decrease in compliance.¹²⁻¹⁴
6. Adequate ventilation is essential to reverse asphyxia arrest and increasing the chest compressions will result in decreased ventilation, which is not desired in post-asphyxia newborns.¹⁵
7. There are several RCTs confirming the benefits of induced hypothermia in postasphyxia newborns associated with significantly fewer deaths and less neurodevelopmental disability at 18-month follow-up. It should begin within 6 hours of birth, continue for 72 hours after birth, and rewarm over at least 4 hours.¹⁶⁻¹⁸
8. Newborns with delayed cord clamping have higher iron stores in infancy, lesser incidence in intracranial hemorrhage, better blood pressure, lesser need for blood transfusions.¹⁹
9. The following guidelines must be interpreted according to current regional outcomes.^{20,21}

- Resuscitation is not indicated in extreme prematurity (gestational age 23 weeks or birth weight 400 g), anencephaly, and some major chromosomal abnormalities, such as trisomy 13 (Class IIa).
- Resuscitation is nearly always indicated in babies with gestational age 25 weeks and those with most congenital malformations (Class IIa).
- In conditions associated with uncertain prognosis in which survival is borderline, the morbidity rate is relatively high, and the anticipated burden to the child is high, parental desires concerning initiation of resuscitation should be supported (Class Indeterminate).

VENTILATION STRATEGIES

Ventilation strategies were examined from 4 perspectives:

- Characteristics of the initial assisted breaths and the role of positive end-expiratory pressure (PEEP)
- Continuous positive airway pressure (CPAP) during or following resuscitation
- Devices to assist ventilation
- Strategies when resources are limited.

Positive Pressure Ventilation (PPV)

To establish initial lung inflation in apneic newborn infants, initiation of intermittent positive-pressure ventilation at birth can be accomplished with either shorter or longer inspiratory times. However, initial peak inflating pressures necessary to:

- Achieve an increase in heart rate or
- Movement of the chest are variable and unpredictable and should be individualized with each breath.²²

Pressures: An initial inflation pressure of 20 to 25 cm of H₂O may be effective in preterm babies, but a pressure of 30 to 40 cm H₂O may be necessary in some term babies.

If pressure is not being monitored, the minimal inflation required to achieve an increase in heart rate should be used.²³

Over inflation of chest in preterms during resuscitation should be avoided.

Assisted ventilation should be delivered at a rate of 40 to 60 breaths per minute to promptly achieve or maintain a heart rate 100 per minute.²⁴

CONTINUOUS POSITIVE AIRWAY PRESSURE

Spontaneously breathing preterm infants who have respiratory distress may be supported with CPAP or intubation and mechanical ventilation. The most appropriate choice may be guided by local expertise and preferences.²⁵

Assisted Ventilation

Ventilation of the newborn can be performed effectively with a flow-inflating bag, a self-inflating bag, or a pressure-limited T-piece resuscitator.

Laryngeal Mask Airway

The laryngeal mask airway indications:

If face mask and tracheal intubation is unsuccessful or not feasible.

The laryngeal mask airway may be considered as an alternative to a face mask for positive-pressure ventilation among newborns weighing 2000 g or delivered at 34 weeks' gestation.²⁶

Use has not been evaluated in:

- Meconium-stained amniotic fluid
- During chest compressions, or
- For administration of emergency intratracheal medications.

Endotracheal intubation may be indicated at several points during neonatal resuscitation:

- Initial endotracheal suctioning of nonvigorous meconium-stained newborns
- If bag-mask ventilation is ineffective or prolonged
- When chest compressions are performed
- For special resuscitation circumstances, such as congenital diaphragmatic hernia or extremely low birth

Indicator of Endotracheal Intubation

- Prompt *increase in heart rate* is the best indicator that the tube is in the tracheobronchial tree and providing effective ventilation.
- Exhaled CO₂ detection is the recommended method of confirmation of endotracheal tube placement (LOE 5).
- Other clinical indicators — condensation in the endotracheal tube, chest movement, and presence of equal breath sounds bilaterally, have not been systematically evaluated in neonates.

Medications and Fluid Administration

Epinephrine

If adequate ventilation and chest compressions have failed to increase the heart rate to >60 beats per minute, then it is reasonable to use epinephrine.

Dose: 0.01 to 0.03 mg/kg *intravenously* (Class IIa)

If intravenous access is not available it can be given by endotracheal route.

Dose: 0.05 mg/kg to 0.1 mg/kg (Class Indeterminate).^{27,28}

Volume Expansion

- Early volume replacement with crystalloid or red cells is indicated for babies with blood loss, not responding to resuscitation. Because blood loss may be occult, a trial of volume administration may be considered in babies who do not respond to resuscitation (Class IIb, LOE C).²⁹
- An isotonic crystalloid solution or blood is recommended for volume expansion in the delivery room rather than albumin (Class IIb). The recommended dose is 10 ml/kg.

Other Drugs

Very rarely a narcotic antagonist (naloxone), sodium bicarbonate or vasopressors may be useful after resuscitation. However, these are not used routinely.³⁰ If naloxone has to be used heart rate and color must first be restored using adequate ventilation. Only IV or IM use is recommended, in absence of clinical data use via endotracheal route is not recommended (Class Indeterminate).

Supportive Therapy

Temperature Control

Newborn infants of 28 weeks' gestation should be completely covered in a polythene wrap or bag up to their necks without drying immediately after birth and then placed under a radiant heater and resuscitated or stabilized in a standard fashion (Class IIa, LOE 2,4,5). Delivery room temperatures should be at least 26°C for infants of 28 weeks' gestation.³¹

Changes Modifiable in Future (Table 1)

- *Delayed cord clamping in nonvigorous babies:* Cord clamping being delayed in babies not requiring resuscitation has been validated however in nonvigorous newborns the data is insufficient. If adequate techniques develop in future, proper resuscitation can be provided with the added benefits of delayed cord clamping.
- *PEEP in early resuscitation:* There are not enough studies at present evaluating the benefits of PEEP in early resuscitation. However in view of the improved functional residual capacity and lung compliance PEEP may provide added benefits in resuscitation.
- *Tidal volume measurement during ventilation:* Both hyperinflating and inadequate inflation can have deleterious effects on the lungs of the preterm hence monitoring of tidal volume in resuscitation may be beneficial to prevent lung injuries.
- *Colorimetric CO₂ detection to assess ventilation in nonintubated patients;* though insufficient data regarding its use, can be used in future to detect obstruction.

Among the prominent changes is now three questions are relevant as compared to the earlier four with color being removed from assessment of signs and more emphasis being laid on placing the baby on the mother's chest for skin-to-skin contact. Precordial auscultation better than umbilical cord palpation for detection of heart rate with increase in heart rate as sensitive indicator of resuscitation efficacy. Pulse oximetry is recommended for assessment of oxygenation and attach probe to right hand or wrist (measure preductal saturations). Shift from 100 percent to 21 percent O₂ for term babies needing PPV,

supplemental oxygen to be started at 90 sec from birth in case of no improvement and use of blender and pulse oximetry is recommended for term babies also. CPAP is now mentioned in the algorithm for persistent cyanosis or labored breathing.

Cord clamping to be delayed till 1 min in neonates not needing resuscitation.

Naloxone is not recommended in routine resuscitation.

Newer Guidelines: Efficacy in Indian Scenario

In this era of evidence based medicine the newer changes advocated in recent guidelines are derived from large studies conducted in several tertiary care centers. Even though the human physiology and effects and management of asphyxia is similar it is the application of these methods that may differ in the Indian rural setting. These guidelines can be adapted without any changes in the tertiary care centers in our country. However, some modifications in the recommendations are warranted to make it more adaptable to our scenario. Some areas of changes which may be considered are:

- Use of pulse oximetry in all preterm babies may not be practically possible in a majority of our newborn care corners and birthing places. Not only is it financially impractical but also the logistics of maintenance and upkeep will be major challenges precluding the introduction of pulse oximeters in the delivery rooms across India. Till such time we may continue with the practice of using color as an assessment tool. Laryngeal mask airway requires expertise and may not be the best option in our setting.
- The use of oxygen blender and CPAP though justified and rational can be used in our tertiary centers, however seems improbable in the rural and more so in the noninstitutional deliveries due to cost logistics of maintenance and the supply of uninterrupted electricity.
- The current recommendation not providing any recommendation with respect to meconium in non-vigorous babies needs to be viewed with caution as meconium is a problem largely seen in the Indian sub-continent and at this point it may seem unethical to deny our vast majority of meconium stained babies' tracheal suction when they need it.

CONCLUSION

About 10 percent of newborns require resuscitation at birth and the prompt availability of trained personnel's can drastically reduce neonatal mortality. Hence, all health workers should be updated regarding the changes in resuscitation guidelines and to be put to use in the best possible way in accordance with the local practices in rural settings.

Table 1: Comparisons for the changes in recommendations

<i>Resuscitation step</i>	<i>Recommendations (2005)</i>	<i>Recommendations (2010)</i>
1. Assessment for need of resuscitation	Four questions <ul style="list-style-type: none"> • Gestation—term or not? • Amniotic fluid—clear or not? • Tone—Good? • Breathing/Crying? 	Three questions <ul style="list-style-type: none"> • Gestation—term or not? • Tone—Good? • Breathing/Crying?
2. Routine care (given if answer to all three question is YES)	<ul style="list-style-type: none"> • Provide warmth • Clear airway • Dry • Assess color 	<ul style="list-style-type: none"> • Provide warmth • Assure open airway • Dry • Ongoing evaluation (color, activity and breathing)
3. Initial steps	<ul style="list-style-type: none"> • Provide warmth • Position; clear airway (if required) • Dry, stimulate, reposition 	<ul style="list-style-type: none"> • Provide warmth • Open airway (no routine suction) • Dry, stimulate
4. Assessment (after initial steps and ongoing)	<i>Look for 3 signs</i> <ul style="list-style-type: none"> • Respiration 	<i>Look for 2 signs</i> <ul style="list-style-type: none"> • Heart rate
4.1. Assessment for need for progressive steps after initial steps	<ul style="list-style-type: none"> • Heart rate • Color 	<ul style="list-style-type: none"> • Respiration (labored, unlabored, apnea, gasping)
4.2. Assessment of heart rate	Palpation of umbilical cord pulsation for 6 sec and multiply by 10	Auscultation of heart at the precordium is the most accurate
5. Positive pressure ventilation (PPV)	<i>Indications are (any 1 out of 3)</i> <ul style="list-style-type: none"> • Heart rate <100/min • Apnea or gasping 	<i>Indications (1 out of 2)</i> <ul style="list-style-type: none"> • Heart rate <100/min • Apnea or gasping
5.1. Indication for PPV	• Persistent central cyanosis despite free flow oxygen	Heart rate
5.2. Assessment of effectiveness of resuscitation steps once PPV is started	Heart rate Color Respiration	Pulse oximetry Respiration
6. Initial oxygen concentration for resuscitation in case of PPV	<i>Term babies (≥37 weeks)</i> <ul style="list-style-type: none"> • Start with 100% O₂ during PPV • If room air resuscitation is started O₂ up to 100% should be given if no improvement within 90 seconds • In case nonavailability of O₂— start room air <i>Preterm babies (<32 weeks)</i> <ul style="list-style-type: none"> • Start with oxygen between 21 and 100% • Advocates use of blender for graded O₂ • Pulse oximetry for targeting SpO₂—85–95% 	<i>Term babies (≥37 weeks)</i> <ul style="list-style-type: none"> • Start with room air (21%) • No improvement in heart rate or oxygenation — use up to 100% to attain target saturations • Use blender for graded increased in delivered oxygen concentrations <i>Preterm (<32 weeks)</i> <ul style="list-style-type: none"> • Initiate resuscitation using O₂ concentration between 30–90% • Uses blended air oxygen mixture judiciously guided by pulse oximetry
7. Peripartum suctioning for neonates born through meconium stained amniotic fluid	<ul style="list-style-type: none"> • No routine oropharyngeal and nasopharyngeal suction • Tracheal suction only in nonvigorous babies born through meconium stained amniotic fluid (MSAF) 	<ul style="list-style-type: none"> • No routine oropharyngeal and nasopharyngeal suction required • Tracheal suction of nonvigorous babies with MSAF still to be continued though evidence for the same is conflicting
8. Initial breath strategy positive pressure ventilation (PPV)	<ul style="list-style-type: none"> • No specific recommendation for short or long inflation time • No specific PIP recommendation • No specific recommendation for PEEP • Guiding of PPV looking at chest rise and improvement in heart rate 	<ul style="list-style-type: none"> • No specific recommendation for short or long inflation time as evidence is conflicting • PIP— for initial breaths 20–25 cm H₂O for preterm and 30–40 cm H₂O for term • PEEP likely to be beneficial for initial stabilization of preterm infants, if provided with suitable equipment (T-piece or flow inflating bags) • Guide the PPV looking at heart rate and oxygenation especially in preterm, chest rise less reliable

CHAPTER 3

Practical Approach to Fluid and Electrolyte Management in Newborns

Anup Jalan

Fluid and electrolyte therapy is a very important component of overall care of a sick neonate. Fluid and electrolyte requirements are a very dynamic phenomenon and require alterations depending on gestation, age or sickness. Premature neonates, particularly those with low birth weight, frequently require parenteral fluids, whose quantity and composition can be highly variable. Correction of fluid and electrolyte derangements is not only important for improving their survival but also is very essential in ensuring good neurodevelopmental outcome.

This topic covers the basic mechanisms for maintaining fluid and electrolyte homeostasis and outlines the factors that govern fluid and electrolyte requirements for term and preterm infants. I describe methods for monitoring fluid and electrolyte balance, discuss potential complications and practical approaches of fluid and electrolyte imbalances.

BODY FLUID COMPOSITION IN THE FETUS AND THE NEWBORN

At birth, the percentage of body weight represented by water is approximately 75 percent in term infants and greater in premature infants (Fig. 1). As gestational age increases, total body water and extracellular water decrease and intracellular fluid content increases. An infant born at 32 weeks' gestation has a total body water and extracellular fluid bodyweight percentage of approximately 83 percent and 53 percent, respectively.

POSTNATAL CHANGES IN BODY WATER COMPARTMENTS

During the first 7 to 10 days of life, all infants experience a reduction in bodyweight, which, in part, represents inadequate calorie intake during this period. However, this physiologic weight loss is largely the result of a

reduction in the extracellular compartment of body water. The precise mechanism for the postnatal contraction of the extracellular fluid compartment is unclear. However, it has been well documented that infants with low birth weight lose approximately 10 percent to 15 percent of the extracellular fluid during the first 5 days of life. This phenomenon is associated with a concurrent diuretic phase resulting in negative fluid and sodium balance.

It is important to recognize that in the first few days of life, physiologic weight loss in an infant with low birth weight represents isotonic contraction of body fluids. The contraction of the extracellular fluid space appears to be part of a normal transitional physiologic process. Perturbations of this normal transitional physiology can lead to

Fig. 1: Total body water (TBW) content and its distribution between the extracellular fluid (ECF) and intracellular fluid (ICF) compartments in the human fetus, newborn and infant from conception until 9 months of age

imbalances in sodium and water homeostasis. In particular, high fluid intake resulting in a lack of extracellular fluid compartment contraction may be associated with a higher incidence of symptomatic patent ductus arteriosus and necrotizing enterocolitis.

FLUID AND ELECTROLYTES CALCULATION

Calculation of fluid requirements in the newborn is based on maintenance needs, deficits and ongoing losses. Critical factors that determine these fluid requirements include gestational age, renal function, ambient air temperature, ventilator dependence, presence of drainage tubes and gastrointestinal losses.

Maintenance Fluids

Maintenance fluid requirements are the quantities of water needed to preserve neutral water balance in the typical preterm or term newborn. The total amount of maintenance fluid required is equal to urine production plus insensible losses. A summary of maintenance fluid requirements during the first month of life for full-term and preterm infants is listed in Table 1. The values in Table 1 are only guidelines; they are to be used as a starting point for prescribing maintenance fluid for infants with low birth weight during the first week of life. Further adjustments must be based on the clinical situation. In particular, close attention must be paid to the patient's volume status and assessment of factors that could increase or decrease the baseline fluid requirements if the clinician is to provide appropriate management of the infant.

Insensible Losses

Insensible water losses are primarily evaporative losses via skin and respiratory tract. In newborn infants, one-third of insensible water loss occurs through the respiratory tract, and the remaining two-thirds occurs through the skin. A number of physiologic, environmental and therapeutic factors (Level of maturity, environmental temperature, humidity, skin breakdown such as burns, omphalocele, phototherapy, double-walled incubator) can influence insensible water loss, making it the most variable component of the maintenance fluid requirements in

newborns. The most important variable is the maturity of the infant because there is an inverse relationship between bodyweight and insensible water loss. A 26 week ELBW baby under a radiant warmer on day 1 may lose over 150 ml/kg/day. Mature babies will lose <30 ml/kg/day. Insensible losses decrease after first few days, as skin thickens.

Urinary Losses

The quantity of water required for the formation of urine depends on two major factors: The degree of renal function and the renal solute load. Under normal conditions, a major determinant of renal water requirement is renal solute load. Renal solute load is derived from exogenous and endogenous sources.

During the first day or two of life, the exogenous solute load of infants with low birth weight is minimal because they usually do not receive electrolytes or protein. Because they are not usually fed enterally, however, delivery of calories by intravenous glucose-containing solutions does not meet basal energy needs. For instance, in the first day or two of life, the basal energy requirement for infants with low birth weight is approximately 50 kcal/kg body weight. If they are given 70 to 90 ml/kg per day of a 10 percent glucose solution, the caloric intake is 35 kcal/kg per day. The infants, therefore, must derive the remaining mandatory energy requirement from an endogenous source; in other words, they must derive energy from catabolism.

The catabolic state produces approximately 6 mOsm/kg per day of an endogenous solute load presented to the kidney. Assuming the infant can produce a maximum urinary concentration of 600 mOsm/kg, then a minimum of 10 ml/kg per day of free water is required to excrete this solute load. As the infant ages, the exogenous intake from parenteral and enteral sources increases, resulting in increased caloric intake. The exogenous solute load therefore increases, whereas catabolism decreases, resulting in a decreased endogenous solute load.

By 2 or 3 weeks of age, an infant consuming 80 to 120 kcal/kg per day has a total solute load of approximately 15 to 20 mOsm/kg per day. Assuming that the infant can produce a maximum urinary concentration of 800 mOsm/kg by this age, thus 20 to 25 mL/kg per day of free water is required to excrete the solute load.

Table 1: Maintenance fluid requirements during the first month of life

Birth weight (g)	Insensible water loss (ml/kg/day)	Water requirements (ml/kg/day) by age		
		Day 1–2	Day 3–7	Day 8–30
<750	100–200	100–200 +	150–200 +	120–180
750–1000	60–70	80–150	100–150	120–180
1001–1500	30–65	60–100	80–150	120–180
>1500	15–30	60–80	100–150	120–180

Other Fluid Losses

Water loss through the gastrointestinal tract from stool output is minimal during the first few days of life, particularly in infants with low birth weight. Once enteral feeds begin, the water loss in the stool is 5 to 10 ml/kg per day. In a growing infant, the amount of water required for new tissue formation should be considered in calculating maintenance fluid requirements. Because infants grow at the rate of 10 to 20 g/kg per day and new tissue contains 70 percent water, the maintenance fluid should provide a net water balance of 10 to 15 ml/kg per day.

Electrolyte Requirements

Maintenance sodium and chloride are usually not provided during the first 1 to 2 days of life due to the relatively volume expanded state of the newborn. Similarly, potassium is not provided in parenteral fluid until urinary flow has been established and normal renal function is ensured. From postnatal days 3 to 7, maintenance sodium, potassium and chloride requirements are approximately 1 to 2 mEq/kg per day. Beyond the first week of life, 2 to 3 mEq/kg per day or more of sodium and chloride are required to maintain the positive electrolyte balance that is necessary for the formation of new tissue. Because of high urinary sodium losses, premature infants may require up to 4 or 5 mEq/kg of sodium per day during the first few weeks of life.

Estimating Pathologic Losses and Deficit Replacement

Many clinical situations require careful estimates of ongoing pathologic losses and replacement of deficits. Commonly encountered conditions include diarrhea with dehydration, chest tube drainage, surgical wound drainage and excessive urine losses from osmotic diuresis. The important guiding principle in managing patients with these conditions is to accurately measure the volume and composition of the pathologic losses. Electrolyte losses can then be calculated by multiplying the volume of fluid losses by the electrolyte content of the respective body fluids.

Estimating replacement for pathologic fluid and electrolyte losses can be difficult, particularly in infants who accumulate fluid and electrolytes in static body fluid compartments. This phenomenon, commonly referred to as third spacing, occurs in several conditions including sepsis, hydrops fetalis, hypoalbuminemia and intra-abdominal infections, as well as following abdominal or cardiac surgery. An infant with necrotizing enterocolitis, for example, often accumulates fluid in the mucosal and submucosal tissues of the small and large intestine as well as in the peritoneal cavity. Under these circumstances, large amounts of fluid, electrolytes and protein can leak into the interstitial tissue and cannot be accurately quantified. Because fluid lost into these tissue spaces does not

contribute to effective arterial blood volume and circulatory balance, these patients can appear edematous even though their intravascular volume is decreased. The most appropriate strategic approach to managing these infants is to replenish the extracellular fluid compartments with colloid and crystalloid.

Monitoring Fluid and Electrolyte Balance

Interpretation of key clinical feedback is a critical part of successful fluid and electrolyte management strategies in newborns. Fluid and electrolyte balance can be achieved by using a meticulous and organized system that obtains pertinent data and applies the physiologic principles outlined in the beginning of this chapter. A careful assessment of clinical indicators of volume status, including heart rate, blood pressure, skin turgor, capillary refill, oral mucosa integrity and fullness of the anterior fontanelle is essential. Other pertinent data that must be monitored include body weight, fluid intake, urine and stool output, serum electrolytes and urine osmolality or specific gravity.

During the first few days of life, appropriate fluid and electrolyte balance is reflected by a urine output of approximately 1 to 3 ml/kg per hour, a urine specific gravity of approximately 1.008 to 1.012 and an approximate weight loss of 5 to 15 percent in term infants and in premature infants with very low birth weight, respectively. Sampling of serum electrolytes can be done at 8- to 24-hour intervals, depending on illness severity, gestational age, and fluid-electrolyte balance. Extracellular volume depletion is manifest by excessive weight loss, dry oral mucosa, sunken anterior fontanelle, capillary refill greater than 3 seconds, diminished skin turgor, increased heart rate, low blood pressure, elevated blood urea nitrogen or metabolic acidosis. Serum sodium, which reflects sodium concentration but not sodium content, could be normal, decreased, or increased in states of volume depletion. Bedside monitoring of weight gain, as an indicator of volume status and growth, is essential for monitoring the adequacy of fluid and calorie intake in sick neonates. Beyond the first week of life, infants should gain approximately 20 to 30 g per day.

Practical Approach to Fluid Therapy

- Most cardiorespiratory stable infants can be started on feeds even on day one. We may start full enteral feeds on infant ≥ 32 week (60 ml/kg).
- In stable infants < 32 wk, small amount of enteral feeds are started and rest of fluid requirements are met with IV fluids. Respiratory support *per se* is not a contraindication to start enteral feeds.
- Most unstable infants are started on IV fluids. IV fluid may be dextrose alone or may be PN (with lipid and

amino acid). Consider starting PN in all infants, on whom significant enteral intake is unlikely in next 4 to 5 days. Otherwise start with plain dextrose solution at rate as per estimated fluid limit. Start at GIR 4-6 mg/kg/min. We may use D10 percent as initiating fluid as long as fluid rate is 60-100 ml/kg. if fluid rate is too low (as in HIE/ATN) or too high (as in extreme prematurity, polyuria etc), we may need to use variable dextrose concentrations so as to match desired GIR of 4-6 mg/kg/min.

- Dextrose concentration of required fluid may be calculated by following formula:

$GIR (mg/kg/min) = Fluid\ rate (ml/kg/day) \times Dextrose\ concentration \times 0.007$

- Once we have calculated required fluid volume and desired dextrose concentration (D), we may make this fluid by mixing two dextrose solutions, one with higher concentration (H) and another with lower (L) concentration. This is done using following computations:
- $Lower\ dext\ conc.\ volume = Total\ volume \times (H-D)/(H-L)$
- $Higher\ dext\ conc\ volume = Total\ volume - Lower\ dext\ conc.\ volume$
- Make desired fluid by mixing calculated amount of these two fluid and give over 24 hr
- Monitor blood sugars intermittently (target range 50-150 mg/dl)
- Guidelines for initiating and adjusting fluid and electrolytes (Table 2)

ELECTROLYTE DISTURBANCES

Hyponatremia

Definition: Serum sodium <130 mEq/L

Causes: Hyponatremia could be either due to:

- a decrease in serum sodium relative to body water content (less often)
- excess of free water (more often).

Pseudohyponatremia is a condition in which concentration of sodium per liter of serum volume is decreased due to addition of serum solids such as hyperlipidemia, hyperproteinemia, however sodium concentration per liter of serum water is normal. Diagnosis can be made by a difference in calculated osmolality ($2 \times Na + BUN/2.8 + Glu/18$) and measured osmolality (by ion electrode method), with later being normal in pseudohyponatremia. Correction factors for raised proteins and lipids:

$Triglycerides (mg/dl) \times .002 = mEq/L\ decrease\ in\ Na$

$Plasma\ protein\ level [g/dl] - 8 \times 0.25 = mEq\ decrease\ in\ Na$

In practice, pseudohyponatremia is extremely uncommon in neonates. Hyperproteinemia is unknown in neonatal period. In settings of hyperlipidemia, a rise in triglyceride by 500 mg/dl will lead to fall in serum Na by 1 mEq/L. Thus, even in situation of s triglycerides as high as 1000 mg/dl, serum sodium will fall by 2 mEq/L. Hence, apart from inherited disorders with hyperlipidemia, hyperlipidemia is an unlikely cause of Hyponatremia.

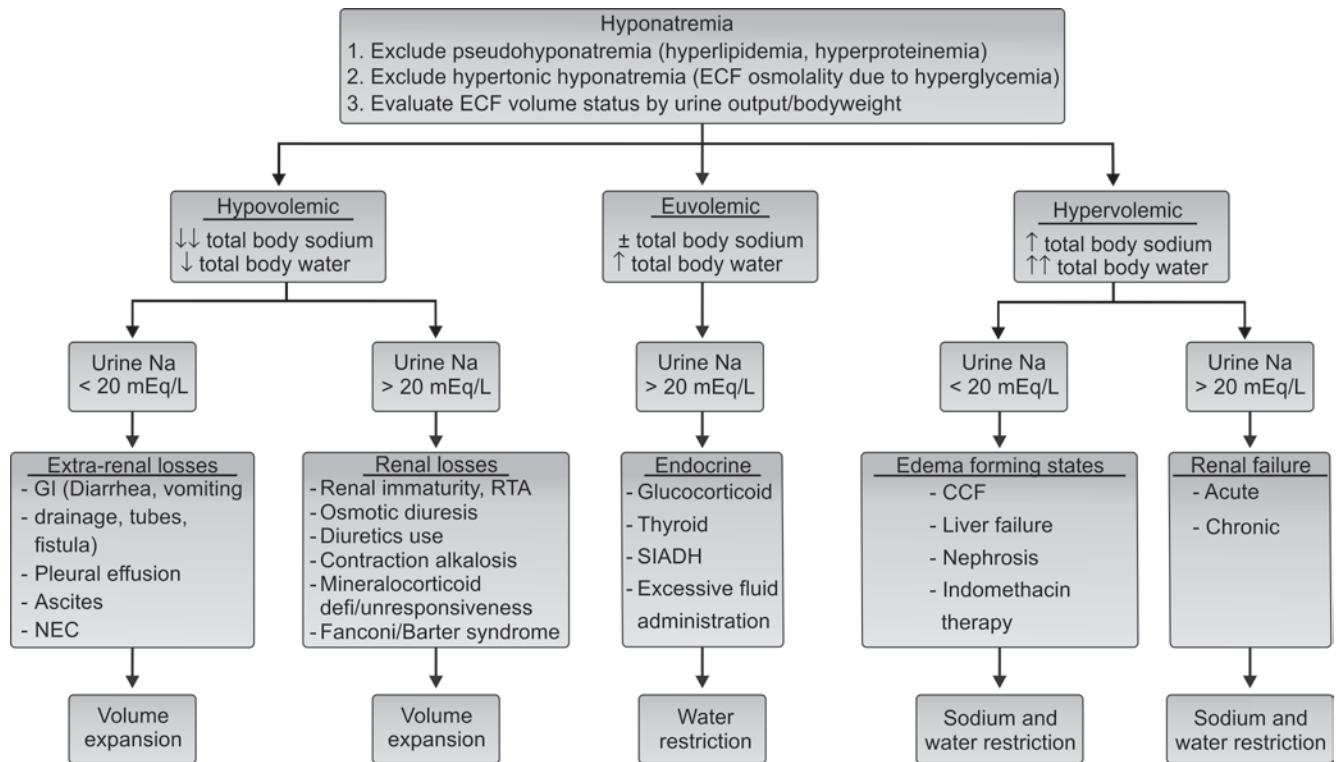

Approach to Hyponatremia (Flow chart 1)

- Hyponatremia is detected either incidentally on routine investigations or on workup of a symptomatic infant.
- Once hyponatremia is detected, evaluated for cause of hyponatremia. Assess weight pattern, urine output and other losses during last 24-48 hrs. (If required investigate for urine sodium and osmolality).
- If there is hyponatremia along with abnormal weight gain: this is a setting of free water access (either due to excessive administration of fluids or due to decreased urine output. Urine sodium and osmolality will be high with ARF and low with SIADH, CCF, liver failure or nephritic syndrome. Treatment required is fluid restriction.

Table 2: Guidelines for initiating and adjusting fluid and electrolytes

	Postnatal Day 1	Adjustment during the prediuretic phase	Adjustment during the diuretic/natriuretic phase
Water	<25 wk: ~150 ml/kg/d 25 - 27 wk: 120 ml/kg/d 28 - 30 wk: 100 ml/kg/d 30 - 34 wk: 80 ml/kg/d >34 wk: 60 ml/kg/d	Increase if: weight loss is >2%/day or serum sodium increases Decrease if: weight increases or serum sodium decreases	Increase by 10 to 30 ml/kg per day if: weight loss is >5%/d or serum sodium is > 150 mEq/L with no sodium intake Decrease by 10 to 30 ml/kg per day if: weight loss is <1%/d
Sodium	None	Usually no sodium is required	Begin 1 to 2 mEq/kg per day if: serum sodium is <135 mEq/L with weight loss or serum sodium is <130 mEq/L with no change or gain in weight
Potassium	None	Usually no potassium is required	Begin 1 to 2 mEq/kg per day if: serum potassium is <5mEq/L and not increasing and urine output is >1 ml/kg/hour

Flow chart 1: Algorithmic approach to hyponatremia

- If there is hyponatremia in absence of abnormal weight gain: This is a setting of total body sodium deficit. This might be due to excessive diuresis/natriuresis or losses through other routes. Urine sodium and osmolality will be high in renal salt wasting and low with extra renal loss. Treatment is replacement of sodium and fluid deficits and increasing daily maintenance to compensate for ongoing losses.

Given below is algorithmic approach to Hyponatremia:

Treatment of Hyponatremia

- In case of free water access, treatment is simply fluid restriction. Target fluid limit should be adjusted so as to achieve a negative fluid balance (less than sum of insensible losses + urine output). This may at times require fluid limit less than 40 to 50 ml/kg/day. (In such setting, we need to give fluid with high dextrose concentration so as to maintain required GIR 4-6 mg/ kg/ min. This will need insertion of central line). Repeat serum sodium every 24 to 48 hr.
- In case of body sodium deficit, replace body sodium. Calculation for sodium deficit is done by following formula:

$$\text{Sodium deficit (mEq)} = 0.6 \times \text{weight} \times (\text{desired Na} - \text{Actual Na})$$
 Correct the deficit by adding calculated sodium in 24 hr maintenance fluid. For every one mEq add 2 ml of 3% saline or 6.5 ml of normal saline.
 Usually, a deficit of 12 mEq/ L should be corrected over every 24 hr. However, if hyponatremia is symptomatic or

serum sodium is less than 120 mEq/L, a rapid correction to a level up to 120 mEq/L is recommended to prevent/control seizures. Give the calculated amount of sodium (to target serum sodium to 120 mEq/L) over 4 to 6 hr as separate infusion and give rest of sodium (maintenance plus remaining deficit) in 24 hr fluid as infusion.

Hypertatremia

Definition: serum sodium >150 mEq/L

Causes:

- Increased sodium intake: Less common (in this there is no weight loss)
 - excessive NS administration
 - excessive sodabibcarb administration
- Decrease body water (hypertatremic dehydration): More common
 - Lactational failure, poor intake, faulty feeding
 - High insensible losses (extremely preterm infant under warmer/phototherapy)
 - Polyuria (DI), diarrhea.

Management of True Hypertatremia

Management of true hypertatremia is simply restriction of sodium intake and monitoring till levels normalize.

Management of Hypertatremic Dehydration

Hypertatremic dehydration is usually a state of both salt and free water deficit with free water deficit being more than sodium deficit, hence resulting in increase sodium

concentration in serum. Treatment consists of correction of both sodium and fluid deficit.

Principle of therapy is to correct both sodium and fluid deficit gradually, so that there is no rapid change in serum osmolality. Any rapid fall in osmolality will lead to transcellular shift of water and hence brain edema.

Goal of Therapy

- Fall of serum sodium 10 to 12 mEq/ kg/ day
- Correction of 7% fluid deficit per day (that means 70 ml/ kg fluid deficit correction over every 24 hr).

Calculations for hypernatremic dehydration are as follows:

Calculate Fluid Deficit

This is equal to degree of dehydration. For example, if there is 10 percent dehydration, that means fluid deficit of 100 ml/kg. If dehydration is 20 percent, it is equal to 200 ml/kg of fluid deficit. As classical clinical signs of dehydration are not reliable in estimating degree of dehydration, estimation of fluid deficit is done by estimating weight loss.

Fluid deficit = expected or preillness weight – current weight

- In older infant, it is easy to get preillness weight, as there are not large variations in body weight over days to weeks and any weight measurement during last close visit may be regarded as true weight. But in a neonate, there is a constant significant change in body weight over even short span.
- There is a weight loss during first few days with regain of birth weight by 7 to 14 days. Subsequently, there is a steady weight gain by 10 to 15 gm/kg/day, provided there is adequate caloric balance.
- If adequate caloric intake has been ensured, then a weight difference from the expected weight (as per scheme given above) should be considered as fluid deficit. For example, if a neonate with birth weight 3 kg comes at day 7 of life with weight of 2500 gm (he was expected to regain his birth weight by this time, hence his expected weight was 3000 gm), fluid deficit may be assumed to be $3000 - 2500 = 500$ gm.
- However, in most circumstances, particularly those associated with poor feeding or lactational failure, there is inadequate caloric intake, and hence assuming a growth velocity of 10-15 gm/kg/day will be erroneous. Rather there might be a negative balance and there may be loss of lean body mass in addition to dehydration. Therefore, all the estimated weight difference cannot be attributed to fluid deficit though the estimation proportion of fluid deficit will be difficult and approximate value only.
- Example: if an infant with 3 kg birth weight presents at 3 weeks of life with poor feeding and hypernatremic dehydration. With his present weight of 2.0 kg, his serum sodium is 180 mEq/L. As per physiologic pattern, he must have regained his birth weight by 7 days

and then for next 2 weeks, he is expected to gain 10 gm/kg of his birth weight every day ($30 \text{ gm daily} \times 14 \text{ days} = 420 \text{ gm}$) so expected current weight is $3 \text{ kg} + 420 \text{ gms} = 3.42 \text{ kg}$ and fluid deficit will be $3.42 - 2.0 = 1.42 \text{ kg} = 41\%$.

- But a calorie deprived infant is not expected to gain and will rather lose 5-10 gm/kg every day. So, if we expect 5-10 gm/kg loss every day (with average of 7 gm/kg, i.e. $21 \text{ gm daily} \times 21 \text{ days} = 440 \text{ gm}$), then expected weight will be $3 \text{ kg} - 440 \text{ gm} = 2.56 \text{ kg}$. The fluid deficit will be $2.56 - 2.0 = 560 \text{ gm} = 22\%$
- Earlier calculation of fluid deficit was overestimation and perhaps later estimate is closer to true fluid deficit in this setting.
- However, in settings of excessive losses (e.g. diarrhea, diabetes insipidus, excessive insensible loss), majority of weight difference may be attributed to fluid loss rather than lean mass loss.

Calculate Free Water Deficit

Free water deficit (liter) = $\text{actual Na} - \text{desired Na} \times 0.6 \times \text{Expected weight (Kg)}$

In this case S. Na at admission is 180 mEq/ L, and desired S. Na will be 145 mEq/L.

Free water deficit: $180 - 145 / 180 \times .6 \times 256 = 0.298 \text{ L} = 298 \text{ ml}$

- As a rough rule, free water deficit is 3 to 4 ml/ kg for each mEq rise in serum sodium. Take factor of 4 if there is pure free water deficit (as in diabetes insipidus) and factor of 3 if there is combined free water and sodium deficit.
- For example, in this case serum sodium has risen by 35 mEq/L (s. sodium is 180 mEq/L and desired is 145 mEq/L). weight for calculation of free water deficit will be $3 \times 2.56 \times 35 = 269 \text{ ml}$.

In this case Na deficit = $0.560 - 0.298 \times 0.6 \times 180 = 28 \text{ mEq}$.

Calculate Final Fluid Composition

Our goal will be to correct the fluid deficit of 560 ml (22%) and Sodium difference of 30 mEq/L (Actual Na 180 mEq/L – Desired Na 145 mEq/L) over 3 days. [goal of therapy is to correct 7 percent fluid deficit per day and 10 mEq/L of fall in S. Na per day]. That means 186 of fluid deficit (560 ml/3) and (sodium deficit of 9.3 mEq (28 mEq/3) sodium deficit to be added in each day's maintenance fluid.

Total fluid for day 1 = maintenance fluid + deficit (186 ml)

Total sodium for day 1 = maintenance Na + deficit (9.3 mEq)

Similarly, fluid is calculated for next two days by adding same amount of fluid and Na deficit in next 2 day's maintenance fluid.

Estimating maintenance fluid requirement for each day: Standard calculation for maintenance fluid requirement is insensible losses + urine output. Only difference

is that urine output may be very low in dehydrated state. Hence, for the first day do not assume maintenance requirement to be in range of 150 ml/kg. In fact, it may be in range of 50 to 100 ml/kg.

- Take caution in estimating maintenance fluid requirements of a neonate with hypernatremic dehydration. Urine output is expected to be low initially during dehydrated state hence it may be appropriate to estimate maintenance fluid requirement approximately 25-50 ml/kg/day or 1-2 ml/kg/hr.
- Add each day's sodium and fluid deficit to this maintenance fluid. In current example, this means 50 ml/kg maintenance fluid + 186 ml/kg of fluid deficit (total 236 ml fluid at rate of 10 ml/hr). Sodium maintenance will be 2-3 mEq/kg = approx 6 mEq + deficit 9.3 mEq = total 15 mEq approx.
- Monitor weight and urine output every 4 to 6 hr and adjust fluid rate to achieve target weight gain of 2 percent every 6 hr or 8 percent in 24 hr. Do not overshoot the weight gain as it will lead to precipitous fall in serum sodium. If weight gain is inappropriately high (urine output is lower than estimated), decrease fluid rate and if weight gain is slow (urine output is higher than estimated), increase the fluid rate. Maintain target weight gain 2 percent every 2 hr or 8 percent every 24 hr.
- Repeat serum sodium every 6 to 8 hr target fall in serum sodium by 3 mEq/L in every 6 hr or 12 mEq/L in every 24 hr. increase fluid rate if fall in serum Na is slow and decrease the fluid rate, if fall is rapid.
- On subsequent days maintenance fluid amount may be increased, as per increase in urine output.

An Alternative Simple Regimen may be as Follows

- It's not that we have to always go through the twisting calculations for correction of hypernatremic dehydration. Though calculations customize the fluid type and volume for the infant's need, they are also based on our assumptions about body losses and may be wrong. Moreover calculation errors may be a disaster. Hence, if one is not comfortable, he may skip calculations to the following regimen.
- You may use N/3 to N/5 saline in D5% as the type of fluid for correction of hypernatremic dehydration. Use N/5 solutions if pure free water deficit is there (diabetes insipidus, etc.) and use N/3 if significant sodium deficit is there along with fluid deficit (diarrhea and other scenarios with body salt losses). In settings of decreased intake, take strength in between two (use N/4 to N/5).
- Fluid rate is calculated in same manner as above. Add maintenance fluid, which should be approximately 50 ml/kg for first day plus 8 percent or 80 ml/kg of fluid deficit over every 24 hr, i.e. a total of 50+80 =130 ml/kg of N/4 saline in D5%. Fluid rate may be later adjusted as per weight gain pattern, as discussed above.

- Over next day you may increase maintenance fluid amount, as urine output improves. Add 80 ml/kg as deficit in maintenance fluid. (for example you may take 100 ml maintenance plus 80 ml deficit. That means a total of 180 ml/kg N/4 to N/5 D5% for second day and so on.
- Keep monitoring weight, urine output and serum sodium every 4 to 6 hr and make appropriate adjustments, till sodium is <150 mEq/L.
- If patient requires acute correction of fluid deficit because of shock, it should be done with NS only @ 20 ml/kg/hr.

One of the most important points in understanding the management of hypernatremic dehydration is anticipating its presence. This entity should be expected in any neonate, who comes with significant weight loss/ poor weight gain/ failure to thrive, etc. If hypernatremic dehydration is not suspected at admission and high rate of hypotonic fluids are started, then enough damage might have incurred by the time serum sodium report is available. Be reasonable in starting fluids in such scenarios. Do not give rapid boluses unless really needed. Try to get serum sodium report as quickly as possible.

HYPERKALEMIA

- Normal S. potassium = 5.5 ± 0.5 mEq/L
- Hyperkalemia >6 mEq/L
- *Causes*
 - Excess administration (calculation error)
 - Acidosis
 - Decreased K clearance: ARF, oliguria, CAH
 - Increase K release: Tissue destruction, hemolysis, internal bleeding, asphyxia, IVH
 - Miscellaneous: Blood/ exchange transfusion
 - Pseudohyperkalemia: Excessively squeezed/ hemolysed sample
- *Clinical Signs*
Brady or tachyarrhythmia, cardiovascular instability or collapse
- *ECG*
Changes progress with increasing K levels
 - Peaked T waves
 - Flattened P waves and increasing PR intervals
 - QRS widening and slurring
 - Finally, SVT/VT, bradycardia and VF
- *Other investigations:*
Blood gas (for metabolic acidosis), calcium, electrolytes, renal functions, urine output
- *Management*
 - Remove all sources of exogenous potassium
 - Rule out spurious hyperkalemia—trauma, thrombocytosis, hyperleukocytosis (TLC >50,000/mm³)
- Repeat serum K (to reconfirm)
- ECG to be done (to look for electrophysiologic effect of hyperkalemia)

- Treatment varies based on the fact whether hyperkalemia is symptomatic or asymptomatic (detected incidently) and on severity of hyperkalemia. If hyperkalemia is asymptomatic and serum potassium levels are <7 mEq/L, conservative management with elimination of potassium from IV fluids and close monitoring may be sufficient.
- If hyperkalemia is severe and/or it is symptomatic, then additional measures are required.
- Goal of therapy is to:
 - Stabilize myocardium (by IV calcium gluconate)
 - Promote intracellular shift (by insulin infusion). In presence of acidosis give bicarbonate correction.
 - Enhance elimination (by exchange resins).

Approach

- Give *Calcium gluconate* (10%) carefully under cardiac monitoring 1 to 2 ml/kg IV as a slow infusion. Repeat as required, till hyperkalemia resolves.
- *Insulin*: Give a bolus of insulin and glucose (0.05-0.1 units/kg of regular insulin with 2-4 ml/kg of 10 percent dextrose. This is followed by continuous infusion of insulin 0.05-0.1 Unit/kg/hr with a parallel neutralizing dextrose infusion drip (250-500 mg/ kg/ hr). run insulin and dextrose infusion separately so that adjustment in dextrose infusion rate can be done so as to maintain euglycemia. 5 units of insulin can be diluted in 50 ml NS and given as 0.1 unit/kg/hr. Dextrose infusion can be given as Dextrose 10 percent at rate of 2.5-5 ml/ kg/hr. Rate may be adjusted according to blood sugars, which should be monitored periodically. If fluid restriction is warranted due to oliguria or overhydration, you may use dextrose 25 percent (through central line) at rate of 1-2 ml/kg/hr.
- *Beta-2-adrenergic stimulation*: Enhances K uptake via stimulation of Na-K ATPase. Salbutamol may be given as Nebulization, though rarely used as primary therapy.
- *Alkalemia*: Sod. bicarbonate may be used 1-2 ml/kg IV, particularly if acidosis is present.
- *Exchange resins*: Na polystyrene sulfonate (Kayexelate) given rectally (1gm/kg with 0.5 g/ml of DW/NS) with a minimum retention time of 30 minutes, repeat every 4-6 hrly (*mainstay of therapy*).

Furosemide: 1 mg/kg iv may increase K excretion, particularly in state of fluid overload.

Peritoneal dialysis and double-volume exchange transfusion in case of refractory threatening hyperkalemia.

Suggested Algorithm

Serum K >6 , Normal ECG

- Eliminate exogenous supplementation
- Monitor K every 6-12 hrly

Serum K >7 , Normal ECG

- Eliminate exogenous supplementation
- Exchange resin (Kayexelate)
- Monitor K every 4-6 hrly.

Arrhythmias/ Serum K >8

- All above measures plus
- Calcium gluconate
- Insulin infusion (with neutralizing dextrose drip)
- NaHCO_3 , if warranted
- Diuretics, if warranted.

Refractory Hyperkalemia

- All above measures plus
- Peritoneal dialysis/exchange transfusion.

HYPOKALEMIA

- Normal S potassium 5.5 ± 0.5 mEq/L
- Significant hypokalemia: Serum potassium <3.5 mEq/L
- *Causes*
 - Spurious hypokalemia: High WBC-Sample in room air uptake of K by WBC
 - Alkalosis (an increase in pH by 0.1 leads to fall in K of 0.6 mEq/L)
 - NG loss, ileostomy drainage, diarrhea, persistent vomiting
 - Renal tubular defects
 - Hyperaldosteronism
 - Drugs: Chronic diuretic use, steroids, digoxin, amphotericin B, aminoglycosides, β -agonist, insulin therapy
- *Clinical features*
 - Hypotonia, ileus, urinary retention
 - Respiratory failure, failed weaning
 - Hypotension
 - Ventricular arrhythmias
 - Cardiac arrest
- *ECG changes*: Prominent U waves, bifid T-waves, flattened T, QTc prolongation
- *Evaluation*: Obtain serum and urine electrolytes and ABG and ECG
- *Management*
 - Reduce/replace renal/GI loss
 - Correct alkalosis, if present
 - Increase potassium intake as needed. Preferable route—Oral if possible. IV Potassium if oral route is not possible or hemodynamically unstable. Increase the potassium supplementation from normal 2 mEq/kg/day to 3-5 mEq/kg/day as infusion over 24 hr). Continue hemodynamic monitoring. Repeat S. potassium every 6 to 12 hr.

- One suggested regimen for potassium concentration in infusate is as follows:

Serum potassium level (mEq/L)	Potassium conc in infusate (mEq/L)
3 – 3.5	30 mEq/L
2.5 – 3	40 mEq/L
2 – 2.5	60 mEq/L
<2 or arrhythmia/hypoventilation	KCl drip 0.5–1 mEq/kg/hr

HYPOCALCEMIA

- Normal calcium value = 9-11 mg/dl
- Hypocalcemia defined as <8 mg/dl in term infant and <7 mg/dl in PT infant
- Total calcium is influenced by serum albumin concentration. A decrease in S. albumin by 1 gm/dl will lead to a decrease in total calcium by 1 mg/dl.
- Physiologically important component is ionized calcium which should be >4 mg/dl.
- In sick infant low total calcium may be because of associated hypoalbuminemia. Ionized calcium may be unaltered in this situation.
- Serum calcium levels are primarily regulated by Vit-D and PTH levels rather than calcium intake.

Causes of Hypocalcemia

- *Early hypocalcemia (1-4 days)*
 - Prematurity
 - Asphyxia
 - Perinatal stress
 - IUGR
 - Maternal diabetes
 - Maternal anticonvulsants
- *Late hypocalcemia (5-10 days)*
 - Hyperphosphatemia
 - Hypomagnesemia
 - Alkalosis, alkali therapy, citrated blood transfusion, furosemide, xanthine use, lipid infusion, phototherapy
 - Vit D deficiency
 - PTH resistance (transient neonatal pseudohypoparathyroidism)
 - Primary hypoparathyroidism (agenesis/DiGeorge syndrome)
 - Secondary hypoparathyroidism (due to maternal hyperparathyroidism)
 - Acquired/inherited disorders of Vit D metabolism
 - Skeletal dysplasia (osteopetrosis)

Evaluation

- *History*
 - Maternal diabetes/hyperparathyroidism
 - Intrapartum events/asphyxia, PT/IUGR
 - Nutritional supply of mother/infant
 - History of drugs intake
- *Physical examination*
 - Features of hypocalcemia: jitteriness, cyanosis, seizures
 - Associated features: PT, CHD, dysmorphism (DiGeorge syndrome)
- *Investigations*
 - Total/ionized calcium
 - Blood gas
 - Magnesium, phosphorus
 - Urinary calcium, phosphorus, magnesium, creatinine
 - Chest X-ray (for thymic shadow)
 - Vit-D metabolite, PTH, calcitonin levels (in unexplained refractory hypocalcemia).

Treatment

- For asymptomatic hypocalcemia in PT infants, treatment threshold is <6 mg/dl.
- For symptomatic hypocalcemia, IV calcium gluconate 10 percent is indicated. Give IV bolus (slow over several minutes) at dose of 2 ml/kg. Subsequently IV calcium should be continued at dose of 75 mg/kg/d of elemental calcium (8 ml/kg/day of 10 percent calcium gluconate) either as 6 hrly boluses or as continuous infusion in par-enteral fluid. Take care of extravasation into soft tissue.
- Usually 2 to 3 days of therapy is sufficient.
- If requirement is prolonged, shift to oral therapy, once infant is ready to tolerate oral feed. Same dose of elemental calcium should be given in form of susp osteocalcium (except in setting of hyperphosphatemia).
- A poor response to calcium therapy may result from concurrent magnesium deficiency. If magnesium deficiency is present (Magnesium level <1.6 mg/dl), magnesium should be given IV/IM, as 50 percent magnesium sulfate in a dose of 0.1 to 0.2 ml/kg, repeat 12 to 24 hr, if needed. Usually, one or two doses are sufficient.
- If hyperphosphatemia is the underlying cause, give oral calcium salt (as carbonate) with low phosphorus formula.
- If vit D deficiency is suspected/proved, 1000 to 2000 IU vit D for 4 weeks is sufficient. Hypoparathyroidism is also treated similarly with 1000 to 2000 IU Vit-D supplementation.

HYPERCALCEMIA

- Defined as serum total calcium >11 mg/dl.
- Clinical signs (unusual below 13 mg/dl) are vomiting, dehydration, hypotonia, seizures, bradycardia, HT, renal function impairment, polyuria, hypercalciuria, nephrocalcinosis, hematuria.

Causes

- *Iatrogenic*: Calcium salts, vit A, vit D, thiazide diuretics, hypophosphatemia
- Neonatal hyperparathyroidism/maternal hypoparathyroidism
- Familial hypocalciuric hypercalcemia
- Distal RTA
- Subcutaneous fat necrosis
- Carbohydrate malabsorption
- William's syndrome
- Blue diaper syndrome
- Hyperprostaglandin E syndrome
- Hypophosphatasia
- Tumor – related

Evaluation

- *History*
 - Rule out iatrogenic causes first
 - Familial/maternal disease
 - Traumatic birth
 - Maternal/neonatal vit A/vit D supplementation, thiazide use.
- *Physical examination*
 - Lethargy, dehydration, hypertension
 - Associated features: elfin facies, CHD, MR, subcutaneous fat necrosis
- *Investigations*
 - Total/ionized calcium, phosphorus, magnesium, alkaline phosphatase, blood gas, protein, creatinine
 - Urinary calcium, phosphorus, creatinine, pH
 - ECG: short QT interval
 - Chest and long bone X-ray (identify demineralization/lytic lesions)

- Renal ultrasound
- PTH, 25 OH- vit-D level, vit-A level

Treatment

- Conservative management is appropriate in mild hypercalcemia.
- If hypercalcemia is associated with hypophosphatemia (due to poor phosphorus supply) emphasis on phosphorus supplementation.
- In moderate to severe hypercalcemia more aggressive treatment is needed.

Discontinue oral/IV calcium and vit D supplementation

- Increase excretion by giving 1.5 to 2 times maintenance fluids
- Furosemide may enhance renal excretion.
- In extreme of case, corticosteroids (prednisolone 2 mg/kg for short period in case of Vit-D excess), calcitonin, bisphosphonates, dialysis and total parathyroidectomy should be considered as appropriate.

CHAPTER 4

Parenteral Nutrition in Neonatal Intensive Care Unit

Neelam Kler, Vivek Choudhury, Naveen P Gupta

ABSTRACT

Newborn nutrition is a vital part of the well-being of an infant. The period of rapid growth in infancy requires careful nutritional support to continue the growth and development that began at conception. The main objectives in feeding infants are meeting nutritional needs, preventing nutritional deficiencies and promoting growth. Moreover, recent evidence suggests that early nutrition has biological effects on the individual with important implications for later health. The goal of nutrition management in preterm infants is the achievement of postnatal growth at a rate that approximates the intrauterine growth of a normal fetus at the same postconceptional age.

INTRODUCTION

Adequately supplying the nutritional needs of preterm infants remains a significant clinical challenge, especially for very low birth weight (VLBW) and extremely low birth weight (ELBW) infants. Although rates of survival of these infants have improved, growth failure is nearly universal, and multiple recent studies have documented the poor growth and the nutritional deficits in this population of infants. At the time of birth, only about 18 percent of ELBW infants are less than the 10th percentile for weight and length, but at 36 weeks corrected gestational age, as they near discharge most of these same ELBW infants are less than the 10th percentile for weight and length. In these infants, full enteral feedings are generally delayed because of the severity of medical problems associated with prematurity, such as immature lung function (which often requires endotracheal intubation and mechanical ventilation), hypothermia, infections, and hypotension. In addition, early enteral feeds are also delayed because of concerns that aggressive feeding may lead to complications such

as feeding intolerance or necrotizing enterocolitis. As a result, the nutritional requirements of VLBW infants are rarely met by enteral feeds in the first two weeks after birth.¹ The impact of early malnutrition can have long-lasting negative effects on central nervous system development and growth. Parenteral nutrition (PN) can meet the goal of providing nutrition at this time.

MAIN CONTENT

Goals of Parenteral Nutrition

There is growing evidence that inadequate nutrition in the first weeks of life of premature infants results in growth failure that is often difficult to correct and may lead to permanent detrimental effects.² The early use of adequate PN minimizes weight loss, and improves growth outcome. Increased protein and energy intakes in the first weeks of life also are associated with improved neurodevelopmental outcome.³ Because adequate enteral nutrition cannot be established in most VLBW infants in their early weeks, PN is initiated to correct *in utero* growth restriction and to prevent subsequent growth failure.

Indications for Starting TPN

- Premature infants <30 weeks gestation and/or <1000g.
- Wt <1500 not expected to receive full enteral feeds for >3 days (Ventilator dependent—HMD, BPD; NEC, major surgeries, etc.)
- Wt >1500 not expected to receive enteral feeds for >5 days (Severe birth asphyxia, ventilator dependent, fulminant sepsis, etc.)
- Absorption problems as in short bowel syndrome
- Surgically correctable GI malformations (Omphalocele, gastroschisis, TE fistula, malrotation, etc.)
- GI catastrophes as NEC

PN for the premature infant includes the following:

- Adequate calories for energy expenditure and growth
- Carbohydrates to prevent hypoglycemia and, in combination with lipids, provide the caloric intake to meet the energy needs of the infant
- Adequate protein intake including essential amino acids to achieve positive nitrogen balance required for growth
- Fatty acids to prevent essential fatty acid deficiency and maximize overall nonprotein energy intake
- Essential nutrients including minerals (i.e. calcium, magnesium, and phosphorus), electrolytes, vitamins, and trace elements (e.g. copper, zinc, and selenium) are needed for growth.

The recommended nutrient needs for medically stable and growing premature infants receiving either parenteral or enteral nutrition is shown in Table 1.

Calorie Requirements

In premature infants, energy requirements must cover both energy needed for energy expenditure (resting metabolic rate, activity and thermoregulation) and for growth. The resting metabolic rate has been estimated to be 40 to 60 kcal/kg per day in parenterally fed neonates maintained in a thermoneutral environment. Each gram of weight gain for growth, including the stored energy and the energy costs of component synthesis, requires between 3 and 4.5 kcal. Thus, an ideal daily weight gain of 15g/ kg (which estimates daily fetal growth) requires an additional caloric requirement of 45 to 67 kcal/ kg above the estimated resting metabolic rate.⁴ The premature infant has an energy requirement of 80 to 100 kcal/ kg per day when nourished parenterally, which is generally lower than the energy requirement needed with enteral nutrition. This lower energy requirement is due to less fecal energy loss (energy excreted), and usually lower energy needs for activity and thermoregulation because of their controlled thermoneutral environment.

Carbohydrates and fat primarily provide the calories for energy. Protein intake including essential amino acids should be sufficient to attain positive nitrogen balance by covering the needs generated by protein turnover (protein

catabolism) and tissue growth. The distribution of non-protein calories derived from carbohydrates and lipids is similar to that of human milk, which is generally about 40 and 45 percent of calories from fat and carbohydrates, respectively.

Studies have shown that mixtures that favor a higher distribution of glucose (i.e. carbohydrates) may result in adverse effects on respiratory metabolism. Surplus calories from glucose result in glucose conversion to fat, which increases the production of carbon dioxide and raises the partial pressure of carbon dioxide (PaCO₂) leading to an increased minute ventilation and respiratory quotient, and a possible rise in oxygen consumption.⁵ In addition, a balanced distribution of calories from glucose and fat favors protein accretion, while intake of glucose—only PN (i.e. without lipids) is associated with protein oxidation.⁶

Fluid Requirements

The percentage of total body water in fetuses decreases from approximately 95 percent early in development to 80 percent by 8 months' gestation and to 75 percent at term.⁷ During the first day after birth, term infants require a minimum of 60 mL/ kg per day to meet maintenance fluid needs (replacing net losses). As infants mature, fluid needs gradually increase to a total of 120 to 150 mL/kg per day to allow for increased renal solute load, stool water output, and growth. Preterm infants have more insensible water losses than term infants due to their large surface area, skin immaturity, and ensuing increased evaporation. Thus, fluid needs are higher on the first postnatal day at 80 to 100 mL/kg per day and increase by 10 to 20 mL/kg per day to a total of 130 to 180 mL/kg per day as preterm infants mature.⁷

Carbohydrate

Glucose is transported across the placenta via facilitated diffusion and is the principal energy substrate for the fetus. The primary storage form of glucose is glycogen, which is only produced during the third trimester. Glucose is the chief energy source for the neonatal brain and is of paramount importance for preterm infants who, in addition to having limited glycogen stores, also have especially metabolically active organs. Endogenous glucose production varies with age and was estimated to be 8 mg/kg per minute in term newborns and 6 mg/kg per minute in preterm infants.⁸ These production rates provide an appropriate starting point for glucose infusion rates in PN for term and preterm infants. The upper rate of glucose administration is dictated by the maximal glucose oxidative capacity for energy production and glycogen deposition. When glucose is given in excess, it is converted into lipid via lipogenesis. This conversion is inefficient, increases energy expenditure, and may have additional clinical consequences via increased carbon dioxide production and

Table 1: Composition of fluid, energy and nutritional intake for stable growing preterm infants

Components, units	Units/kg/day	
	Parenteral	Enteral
Water, ml	120–160	135–190
Energy, kcl	90–100	100–130
Protein, g	3.0–3.8	3.4–4.3
Fat, g	3–4	5.3–7.2
Carbohydrates, g	9.7–15	

exacerbation of lung disease.⁹ The maximum glucose oxidation capacity is 12 mg/kg per minute in term newborns and preterm infants receiving long-term PN and generally should not exceed this concentration.

The minimum recommended blood glucose concentration is 45 mg/dL (2.5 mmol/L). Despite limited glycogen storage capacity, ELBW infants often experience episodes of hyperglycemia during the first few postnatal days. This may be due to surges in glucose production caused by birth-related increases in catecholamines, possibly compounded by an exogenous supply of catecholamines and inotropic drugs, a decrease in endogenous production of insulin, and an increase in peripheral and hepatic insulin resistance.¹⁰ In addition, ELBW infants often fail to suppress endogenous glucose production completely in response to an exogenous supply of PN glucose. Although there is no consensus definition of hyperglycemia, especially in ELBW infants, a suggested range may be 150 to 220 mg/dL (8.3 to 12.2 mmol/L). The primary concern for hyperglycemia in infants is its association with death, prolonged hospitalization, intraventricular hemorrhage grades 3 and 4, necrotizing enterocolitis, and late-onset bacterial and fungal sepsis.¹¹ Early AA supplementation on the first day after birth seems to stabilize high blood glucose concentrations by stimulating endogenous insulin secretion. Other interventions for hyperglycemia include reducing the glucose infusion rate or treating with intravenous insulin.¹¹ Of note, a Cochrane review evaluating these two strategies for treatment of hyperglycemia found no difference in death or serious morbidities.

There is also a concern about the potential risk of lactic acidemia in infants receiving high insulin and glucose administration. Because the safety of insulin therapy and its impact on hyperglycemia-related morbidities have not been established, the consensus in the literature points toward incrementally decreasing the glucose infusion rate to approximately 4 mg/kg per minute and reserving insulin use for infants whose blood glucose concentrations are greater than 250 mg/dL (13.9 mmol/L) while receiving this infusion rate.

Proteins

The delivery of adequate intakes of both protein and energy, and an optimal mixture of essential/nonessential amino acids is required to achieve a positive nitrogen balance, which results in protein accrual and growth.¹² With no amino acid intake, VLBW infants lose the equivalent of 0.5 to 1 g/kg per day of protein due to protein catabolism in the first days after birth. The impact can be seen in the following example. A 26-week gestation 1,000 g birth weight infant begins with body protein stores of approximately 88 g. Without any protein intake, the infant loses approximately 1.5 percent of total body protein per day. At the same time, the fetus *in utero* accumulates

approximately 2 g/d of body protein. To achieve this rate of accretion, the placenta supplies substantially more than 2 g/kg per day of amino acids to the developing fetus.¹³ After only 3 days without protein intake, body protein stores are reduced by 5 percent from birth and are 10 percent less than a fetus of comparable age. It is obvious that significant body protein deficits can and most often do accumulate rapidly in ELBW infants in early postnatal life, particularly if the initiation of intravenous amino acids is delayed for even a few days after birth (Fig. 1).

Protein accretion rates by fetuses at 24 to 25 weeks', 27 to 28 weeks', and 30 to 32 weeks' gestation have been estimated to be 4.0, 3.6, and 3.3 g/kg per day, respectively.¹⁴ Infusion of AA with glucose as early as the first postnatal day decreases protein catabolism and enhances net protein accretion.¹⁵ Thus, reducing the number of hours that infants receive suboptimal nutrition (without AAs) has been emphasized recently as an important goal of neonatal intensive care. The purpose of early AA supplementation is to provide preterm infants with substrate that promotes protein deposition that closely approximates fetal energy production and growth. For most preterm infants, 1.0 to 1.5 g/kg per day of intravenous AA along with glucose prevents protein catabolism.¹⁶ When non-protein energy intake is 80 to 85 kcal/kg per day and AA intake is 2.7 to 3.5 g/kg per day, nitrogen retention and growth might actually approach the intrauterine rate. Recent studies have challenged the older practice of starting at 0.5 to 1 g/kg per day of AA and gradually advancing the AA infusion rate.^{17,18} In a retrospective study, Valentine and associates¹⁵ suggested that providing 3 g/kg per day of AA within 24 hours of birth to very low-birth weight (VLBW) infants was safe and associated with better weight gain and shorter duration of PN administration. ELBW infants may require up to 4 g/kg per day of intravenous AA to maintain stores and promote growth. More research is needed to establish the optimal AA requirements in critically ill infants and in those who have sepsis and renal and hepatic dysfunction. For a fixed nitrogen intake, nitrogen retention increases with increasing energy intake from 50 to 90 kcal/kg per day. As a result, one needs to consider both nitrogen and energy intake in order to optimize a positive nitrogen balance.

Fig. 1: Protein accretion in intrauterine life and if only glucose is given postnatally

The major concerns about early and aggressive delivery of AA, especially to ELBW infants, are the development of azotemia, hyperammonemia, and metabolic acidosis. These complications of PN were reported using earlier AA preparations and rarely occur with current crystalline solutions. Blood urea nitrogen (BUN) represents the complex interaction of hydration status, renal function, energy quality and quantity, and degree of illness. Rising BUN values are, therefore, not just a reflection of the ELBW infant's intolerance to AA infusion.

Composition

The essential amino acids in PN include isoleucine, leucine, lysine, methionine, phenylalanine, threonine, tryptophan, and valine. In the premature infant, other amino acids may be conditionally essential because the premature infant has a limited ability to synthesize them. They include *cysteine*, glutamine, glycine, histidine, taurine, and tyrosine.¹⁹

The first parenteral amino acid solutions used in neonates were hydrolysates of fibrin or casein. Concerns about these first-generation solutions included high concentrations of glycine, glutamate, and aspartate; the presence of unwanted peptides; and high acidity. Hyperammonemia and acidosis in the early 1970's were associated with the use of the first-generation solutions in neonates. The second generation of amino acid solutions consisted of crystalline amino acid mixtures. The amino acid pattern of these mixtures reflects that of high-quality dietary proteins, with large amounts of glycine and alanine and the absence of glutamate, aspartate, tyrosine, and cysteine.

The current solutions include modifications of crystalline amino acids for use in pediatric patients (Table 2). Aminosyn PF (Abbott Laboratories, North Chicago, IL) and TrophAmine (B Braun, Irvine, CA) are the two parenteral amino acid solutions commercially available in the United States that are recommended for use in neonates. Primene (Baxter Laboratories, Portugal) has an amino acid pattern closely resembling that of TrophAmine, although its composition was derived from fetal and neonatal cord blood amino acid concentrations. In India, Aminoven is the amino acid preparation made by Frasenius Kabi. There is no clear evidence that one amino acid mixture is superior to another in promoting nitrogen retention.

Cysteine and glutamine: It has been proposed that supplementation of *cysteine* and glutamine will improve patient outcome. One possible mechanism is supplementation of these two amino acids improves glutathione synthesis.²⁰ Glutathione is a major intracellular antioxidant and its primary function is to protect cells from free-radical damage (e.g. peroxides). The liver synthesizes glutathione from cysteine, glutamine, and glycine. However, in a trial that randomly assigned standard (45 mg/kg per day) and high dose of cysteine

Table 2: Composition of different amino acid preparations

	<i>Aminosyn-PF</i> (Abbott) (mg/dL) (10% solution)	<i>TrophAmine (B</i> <i>Braun)</i> (mg/dL) (10% solution)	<i>Primene</i> (Baxter) (mg/ dL) (10% solution)
Histidine	312	480	380
Isoleucine	760	820	670
Leucine	1,200	1,400	1,000
Lysine	677	820	1,100
Methionine	180	340	240

Aspartic acid	527	320	600

(81mg/kg per day), there were no differences glutathione concentration and synthesis, and the plasma levels of cystine between the two groups.²¹

Lipids

Intravenous lipid administration provides essential fatty acids (i.e. linoleic and linolenic acids) that cannot be synthesized by humans and is an important nonprotein source of energy. Small amounts of essential fatty acids (approximately 4% of caloric intake or 0.5 g/kg per day) are required to prevent essential fatty acid deficiency. Without supplementation, clinical manifestations of fatty acid deficiency (such as dermatitis, thrombocytopenia, and increased likelihood of infection and failure to thrive) become apparent by the end of the first week after birth.

Intravenous fat emulsion (IL) formulations used in premature infants contain varying combinations of soybean, safflower, or fish oils, with glycerin and egg yolk phospholipids added as emulsifiers (Table 3). When given early as PN, intravenous lipid prevents essential fatty acid deficiency, provide needed energy for tissue healing and growth, and balance the distribution of non-protein calories.²²

Table 3: Composition of different IV lipid preparations

	Soy	Soy/Safflower	Soy/Olive	MCT/LCT
16:0 (%)	11	7.5	13	4.5
18:0 (%)	4	4	3	1.5
18:1 (%)	24	18	60	13
18:2n-6 (%)	55	66	18	27
18:3n-3 (%)	8	4	2	4
Triglyceride (g/L)	200	200	200	200
Phospholipid (g/L)	12	12	12	12
Glycerol (g/L)	22	22	22	22

IL has been given to premature infants who have been severely ill on the first day of life without short-term adverse effects.²³ In one review, there were no differences on growth, the risk of lung disease, and overall morbidity and mortality between early (defined as ≤ 5 days after birth) and late use of IL.²⁴

10 versus 20 percent IL: IL is available in two different concentrations, 10 and 20 percent solutions. In premature infants, at similar or even greater doses of IL, the 20 percent IL solution appears to be better tolerated because the 10 percent solution requires a larger administered volume and is associated with a poorer clearance of triglycerides due to interference from lipoprotein X. The accumulation of lipoprotein X appears to be due to the higher ratio of phospholipids to triglycerides in the 10 percent solution.²⁵ As a result, at the same dose of lipid, infants who receive 20 percent IL solution compared to those who receive 10 percent solution better tolerate and utilize the infused lipids as demonstrated by their lower serum concentrations of triglyceride, cholesterol, and phospholipid.

Continuous vs intermittent infusion: IL can be infused either continuously or intermittently. In the premature infant, intermittent infusion (administered over less than 24 hours) appears to produce higher and more variable serum triglyceride concentrations than continuous infusion (over a 24 hour interval) if both are given at the same lipid dose.²⁶ As a result, the use of continuous infusion of intralipids over 24 hours is advocated.

Measurement of serum triglycerides is the preferred method for monitoring clearance of infused intravenous lipid. Triglyceride concentrations up to 150 mg/dL (1.7 mmol/L) are acceptable; some intensive care units tolerate up to 200 mg/dL (2.3 mmol/L) before decreasing the lipid infusion.

Complications

IL complications in the neonate include the following:

- The risk of hyperlipidemia and hypertriglyceridemia increase with decreasing gestational age and sepsis. A short-term decrease in the lipid infusion rate is usually

sufficient to normalize serum lipid levels with a goal of maintaining serum triglyceride below 150 mg/dL.

- Although there is no direct evidence that IL increases indirect hyperbilirubinemia, there is a theoretical concern that fatty acids may displace bilirubin from albumin-binding sites leading to an increase in free serum bilirubin. As a result, IL rates are limited to less than 3 g/kg per day in causes of extreme hyperbilirubinemia.
- Some studies have shown that IL may interfere with pulmonary oxygenation by altering pulmonary vascular tone and pulmonary artery pressure through thromboxane-mediated pathways or by the formation of free radicals (e.g. hydroperoxides). However, other studies have shown that the use of IL, even when administered within the 12 hours of birth, was not associated with impairment of pulmonary function.

New lipid formulation: A newer IL formulation (Omegaven) utilizes fish oil, which contains long-chain polyunsaturated fatty acids (e.g. docosahexaenoic acid [DHA] and eicosapentaenoic acid [EPA]). This formulation was designed to replace the plant fatty acids (e.g. plant phytosterols) derived from soy-bean lipid emulsions, which have been thought to be proinflammatory and contribute to liver damage. In one study of infants with short bowel syndrome, reversal of cholestasis due to prolonged PN exposure was quicker in 18 infants who received Omegaven compared to 21 historical controls who received soybean emulsions (9.4 versus 44 weeks).²⁷ In addition, the Omegaven group compared to the soybean emulsion group had fewer deaths (2 versus 7) and liver transplantations (0 versus 2). However, randomized controlled trials are needed to determine whether this formulation is more beneficial than the standard IL formulations used in premature infants.

Practical Tips for Lipid Infusion

- Use of 20 percent lipid emulsion is preferable to a 10 percent solution to decrease the risk of hypertriglyceridemia, hypercholesterolemia, and hyperphospholipidemia.
- Initiate lipids at starting dose of 0.5 or 1.0 g/kg per day.
- Plasma triglycerides are monitored after each increase in dose, and concentrations are maintained at less than 200 mg/dL (2.26 mmol/L).
- If the infant has severe hyperbilirubinemia or severe respiratory disease without evidence of PVR, provide lipids at 0.5 to 1.0 g/kg per day, maintaining a serum triglyceride value of no greater than 200 mg/dL (2.26 mmol/L)
- Maximum lipid dosage is usually 3 g/kg per day.
- The lipid infusion hourly rate correlates best with plasma lipid concentrations. Hourly infusion should not exceed 0.12 g/kg per hour.

Minerals

Sodium, potassium and chloride are essential minerals for survival. In VLBW infants, sodium intake should be restricted during first phase of fluid balance to reduce risk of bronchopulmonary dysplasia.²⁸ Till 6 to 10 percent of weight loss has occurred sodium should not be added to PN. Potassium should not be added till diuresis sets in. Sodium and potassium are added to PN usually from day 3 onwards, depending on serum levels. Sodium and potassium can be given as chloride, lactate, or phosphate salts. Infants who receive electrolytes solely as chloride salts may develop hyperchloremic metabolic acidosis. Chloride is generally given as sodium chloride. Estimated and advisable intakes are based on accretion studies and urinary and fecal losses from balance studies completed in the late 1970s.

In premature infants, inadequate intakes of calcium and phosphorus result in bone undermineralization. Clinical manifestations depend upon the degree of impaired bone mineralization and may include osteopenia of prematurity, rickets, and fractures. Bone undermineralization may affect chest wall stability leading to atelectasis and an increased risk of chronic lung disease. Although the net retention is dependent upon the intake of these minerals, the intakes are limited by the solubility of Ca and P in PN solution. Because Ca and P solubility are affected by pH, amino acid concentration and source (e.g., cysteine increases Ca and P solubility), and temperature of the PN solution, adjustment of these factors can increase Ca and P solubility and intake.²⁹ To optimize solubility during PN preparation, P is added first and Ca is added as the last step. The optimal ratio of Ca to P in PN is generally between 1:1.3 and 1:1.7 by weight and nearly a 1:1 molar ratio. Lower ratios result in elevated urinary and serum P suggesting inadequate utilization of P because of insufficient Ca intake. Presently, phosphorus preparation is not available in India. Isolated calcium supplementation can lead to hypercalcemia and hypercalciuria, so calcium levels need to be monitored. The doses of various electrolytes and minerals are shown in Table 4.

Table 4: Recommended doses of electrolytes and minerals

Recommended doses of electrolytes and minerals

Electrolyte/Mineral	Intake
Sodium (meq/kg/d)	0–3
Potassium (meq/kg/d)	0–2
Chloride (meq/kg/d)	0–5
Calcium (mg/kg/d)	60–80
Phosphate (mg/kg/d)	45–60
Magnesium (mg/kg/d)	4.3–7.2

Vitamins

Parenteral vitamins are usually applied as a mixture of different vitamins. Vitamins should be added to lipid emulsion to increase stability and reduce peroxide formation.³⁰ Vitamin induced peroxide load can be reduced by shielding of tubing from light exposure.³¹ Except vitamin K, all vitamins should be supplemented daily. Adult MVI is the only preparation available in our country. It contains benzoic acid as stabilizer which is not recommended for neonates and should be used with caution. The dose of adult MVI is 0.5 ml/kg (comparing parenteral vitamin supplement doses as suggested by ESPGHAN with constitution of adult MVI).³² It is added on day 1. Pediatric MVI is currently not available in India. Separate preparations of fat-soluble and water-soluble vitamins suitable for neonates are not available in India.

Trace Elements

In utero accretion of trace elements primarily takes place in the final trimester of pregnancy. As a result, premature infants are at risk for deficiency of these nutrients because of their low body stores and increased requirements for growth. Calculated daily intake needs for the following trace elements are based upon the birth weight and intra-uterine accretion rate.³³

Recommended intakes for trace elements are as follows:

- Zinc: 400 µg/kg
- Copper: 20 µg/kg
- Chromium: 0.4 µg/kg
- Manganese: 10 µg/kg
- Selenium: 2 µg/kg.

The only trace elements recommended from the first day PN are zinc and selenium. The other trace elements are not needed until after two weeks of age. Iron, another trace element, is not needed in the first few weeks after birth and is not routinely added to PN. In India, the preparation of trace elements is available in form of Celecel.

Preparations of parenteral nutrition along with manufacturer are listed in Table 5.

Infusion Routes

PN may be infused via peripheral and central catheters. Peripheral infusion typically is used for short-term nutrition support. Peripheral vein osmolarity tolerance ranges from 700 to 1,000 mOsm/L. The osmolarity of glucose solutions rises from 255 to 1,020 mOsm/L with increasing concentration from 5 to 20 percent, respectively. Generally, glucose concentrations of 12.5 percent or less are well tolerated by peripheral veins as long as no other osmolarity-increasing agents are added. Central infusion of PN is delivered via central venous catheters and is the preferred route for long-term PN.

Table 5: Market preparations available in India

<i>Constituent</i>	<i>Preparation</i>	<i>Manufacturer</i>	<i>Availability</i>
Dextrose	5%, 10%, 25%, 50%		25, 100, 500
Amino acids	Aminoven infant 6%, 10%	Fresenius Kabi India pvt. limited	100 ml
	Primene	Baxter health care	100 ml
Lipids	Intralipid 10% PLR	Fresenius Kabi India Pvt. Ltd	100
	Intralipid 20% PLR	Fresenius Kabi India Pvt. Ltd	100
	Omegavan	Fresenius Kabi India Pvt. Ltd	100
	Clinoleic 20%	Baxter health care	500
Trace elements	Celecel 4	Claris health sciences	1,3,5
	Celecel 5	Claris health sciences	1,3,5

Table 6: Monitoring of parenteral nutrition

<i>Monitoring of parenteral nutrition</i>		
Parameter	Initial period	Established PN
Weight	Daily	Daily
Length		Weekly
Head circumference		Weekly
Blood sugar	Twice daily	Once daily
Urine sugar	Once daily	Once daily
Serum sodium, potassium, chloride	Every 24-48 hourly, can be done more frequently depending on clinical situation	Once weekly
Calcium, phosphorus, magnesium	Every 24-48 hourly, can be done more frequently depending on clinical situation	Once weekly
Urea, creatinine	48-72 hours	Once weekly
Serum triglyceride	Before initiating and with increment of each dose	Once weekly
Liver function tests	Before initiating lipids	Depending on clinical signs
Hemogram	Depending on clinical needs	Once weekly

Timing and Contents

In ELBW infants, PN should be administered within the first day of life to provide adequate nutrition to minimize early weight loss and protein breakdown, and improve growth outcome. Balancing the distribution of calories between nonprotein sources (i.e. lipids and carbohydrates) and protein sources is critical to optimize protein accretion and avoid adverse effects upon respiratory metabolism and protein oxidation.

The contents of early PN (on the day of birth or soon thereafter) include the following:

- Glucose starting at 4 mg/kg per minute (5 g/kg/day) and slowly increasing to 12 mg/kg/min over several days.
- Amino acids at 3 g/kg per day with increasing increments as tolerated to 4 g/kg per day.
- Lipids at 1 g/kg per day with increasing increments as tolerated to 3 g/kg per day. (See 'Lipids' above)

- Electrolytes are not initially included in early PN but added as needed based upon laboratory evaluation.
- *Other nutrients:* Calcium (60 to 80 mg/kg per day) and multivitamins.

Monitoring

Laboratory monitoring is required to adjust the contents of PN to avoid excesses or deficiencies of any given nutrient and to monitor for PN-associated complications, such as cholestasis and metabolic bone disease. The following laboratory tests should be obtained in any infant who is receiving PN (Table 6).

Complications

Monitoring and adjusting the PN contents can avoid many of the reported PN-associated complications in premature infants, such as electrolytes, glucose, Ca, and P abnormalities.

However, the following significant complications due to PN still may occur in premature infants:

- *Cholestasis*: Cholestasis is a serious complication of PN and is manifested by jaundice due to a direct hyperbilirubinemia.
- *Infection and sepsis*: Line infection is a common complication of PN in premature infants. The two most common bacterial agents are *Staphylococcus epidermidis* and *Staphylococcus aureus*. In the ELBW infants, candidal infections have increased in frequency and are associated with the administration of PN and the use of central venous catheters
- Other line complications include infiltration and potentially skin sloughing, and air embolus.
- Bone disease may occur if adequate nutrients are not provided.

Summary and Recommendations

In the first weeks after birth before adequate enteral nutrition can be established, parenteral nutrition is initiated to help treat *in utero* growth restriction and to lessen growth failure in very low birth weight premature infants (birth weight less than 1500 g).

Composition

- *Energy needs*: Parenteral nutrition (PN) should provide sufficient calories for energy expenditure (resting, metabolic rate, activity, and thermoregulation) and growth. The premature infant who receives parenteral nutrition has an energy requirement of 80 to 100 kcal/kg per day. Carbohydrates and fat primarily provide the calories for energy.
- *Carbohydrates*: Glucose is the carbohydrate used in PN and is a major source of caloric intake needed to meet energy needs. Exogenous glucose is needed after delivery to prevent hypoglycemia. In our practice, we start a glucose infusion rate at 4 mg/kg per minute and advance the rate daily, as tolerated, by 1 to 2 mg/kg per minute to a maximum of 11 to 12 mg/kg per minute. Serum glucose should be monitored because premature infants, especially extremely low birth weight (ELBW) infants (birth weights <1000 g), are susceptible to both hypo- and hyperglycemia.
- *Amino acids*: The delivery of adequate intakes of both protein and energy, and an optimal mixture of essential/ nonessential amino acids are needed to achieve a positive nitrogen balance required for growth and to prevent protein turnover. Early administration of amino acids within the first 24 hours of life prevents protein breakdown and is well tolerated. In our practice, we start an amino acid infusion rate at 3 g/kg per day with increasing increments as tolerated to 4 g/kg per day.

- *Lipids*: Intravenous lipid (IL) administration provides essential fatty acids (i.e. linoleic and linolenic acids) that cannot be synthesized by humans and is an important nonprotein source of energy (Table 4). We initiate IL infusion as a continuous infusion using a 20 percent solution at a dose of 1.0 g/kg per day and advance as tolerated to a target of 3 g/kg per day. A dose of 4 g/kg per day occasionally is used in a chronically-ill infant unable to tolerate enteral feedings. (See 'Lipids' above.)
- *Other nutrients*: Other essential nutrients include carnitine, minerals (calcium, magnesium, and phosphorus), vitamins, electrolytes (sodium, potassium, chloride, and acetate), and trace elements (copper, zinc, and selenium) required for growth.

Administration and Complications

- Parenteral nutrition (PN) can be infused through peripheral or central veins. The choice is dependent upon the expected duration of PN. If the infant is expected to require PN for more than two weeks, a central line should be inserted as a more concentrated formulation can be delivered providing calories required for growth.
- In ELBW infants, PN should be administered within the first day after birth to provide adequate nutrition to minimize early weight loss and protein breakdown, and improve growth outcome. The composition of early PN in ELBW includes glucose, amino acids, lipids, vitamins, calcium, and heparin.
- In patients who require ongoing administration of PN, caloric concentration is increased to provide adequate calories for growth. In addition, trace elements, phosphorus, magnesium, and cysteine are added to PN.
- Laboratory monitoring is required to adjust the contents of PN to avoid excesses or deficiencies of any given nutrient and to monitor for PN-associated complications. PN-associated complications include cholestasis, line infection and sepsis, infiltration and sloughing of the skin, and air embolus.

CHAPTER 5

Feeding of Low-birth-weight Infants

Pankaj Garg, Vivek Choudhary

INTRODUCTION

Newborn nutrition is a vital part of the well-being of an infant. The period of rapid growth in infancy requires careful nutritional support to continue the growth and development that began at conception. The main objectives in feeding infants are meeting nutritional needs, preventing nutritional deficiencies and promoting growth.¹ Moreover, recent evidence suggests that early nutrition has biological effects on the individual with important implications for later health.

Low-birth-weight (LBW) infant is one who weighs less than 2500 grams at birth. Every year 20 million LBW infants are born in the developing world and 40 percent of these are born in India. Low-birth-weight infants are a heterogeneous group and would consist of preterm infants (born <37 weeks of gestation and weighing less than 2500 gm as well as full term infants if they weigh less than 2500 gm and the feeding guidelines would vary from one group to the other.

FEEDING PRINCIPLES FOR FULL TERM LBW INFANTS

Human milk is the recommended nutritional source for full-term infants for at least the first six months of post-natal life (54th WHA). The advantages of breastfeeding are not limited to childhood period but extend much beyond in adulthood as well.

- Reduction of infection (diarrhea, acute respiratory tract infections, otitis media, necrotizing enterocolitis, late onset sepsis)
- Protection against allergies: less chance of eczema, milk allergy and asthma
- Reduction of obesity/diastolic blood pressure by 2 mm Hg/ Type II DM/ leukemia/breast cancer

- Better cognition
- Saves money/social issues
- Reduction of under five child mortality by 13 to 15 percent in India
- Maternal benefits.

Knowing so many benefits of breastfeeding, it is strongly being emphasized by all agencies (WHO, AAP, IAP) to promote breastfeeding till 6 months but the exclusive breastfeeding rates in our country according to latest NFHS III is 46 percent which is low from all standards. Understanding that the incidence of true lactation failure is only 1 percent, there are other problems which can be sorted out by various practical solutions apart from increasing awareness:

- Establishment of antenatal clinic for breastfeeding promotion/nipple examination by obstetricians or pediatricians or any health care worker.
- Feeding in first hour of life to be emphasized which has been incorporated as essential part of Newborn Resuscitation Program and Kangaroo Mother Care.
- Employment of lactation nurses/Counselors in hospitals to help the mothers in actually initiating and maintaining lactation.
- Special emphasis on babies born to LSCS mothers like pain management/different positions/ bedding in/incision line care, etc.
- Promotion of breast milk expression techniques (by manual techniques or breast pumps) would help pre-term babies, working mothers or if mother and baby are separated because of any reason.

After breastfeeding, the second best option for milk in first one year of life is infant term milk formula with composition as close to mothers milk as possible. But the commonest milk consumed by Indian infants is cow's or buffalo's milk which is definitely with lots of side effects namely

iron deficiency anemia, vitamins C and D deficiency disorders, increased risk of infections, increased renal solute load to kidneys especially important during acute diarrhea episodes and most important lack of DHA in bovine milk which is of paramount importance for brain and retina growth. Because of these serious limitations American Academy of Pediatrics recommends against use of cow's milk till one year of age.^{2,3} Pediatric academies of Canada, Scotland and UK recommend not using cow's milk till 9 months of age. The age cut off of 9 to 12 months is based on the demonstration of microscopic bleeding from intestines in infants fed unmodified bovine milk till this age.

Supplementation of Exclusively Breastfed Infants

Because of widespread prevalence of vitamin D deficiency disorders in infants, AAP guidelines⁴ suggest to start vitamin D (400 IU/d) even in exclusively breastfed infants. Though there are concerns regarding exposure of infants to sunlight and later developments of skin cancer in white races; we do not have any Indian figures to support or negate these observations and as of now we do recommend sun exposure for vitamin D insufficiency.

Iron supplementation is started at 6 months of age as later supplementation has been associated with increased prevalence of iron deficiency states whereas earlier supplementation is also not without risks of infection (especially in malaria endemic zones) and poor growth.

FEEDING PRINCIPLES FOR PRETERM LBW INFANTS

This group can be subdivided in two smaller groups:

- Infants between 32 weeks and <37 weeks; 1800 gm to <2500 gm
- Infants <32 weeks and <1800 gm.

For the first group, the feeding principles should be on the same as that of full term infants in most situations and should be on direct breastfeeds. The special need of nutrition comes for the second group. The European Society of Paediatric Gastroenterology and Hepatology has given its recommendations for this group which is at a distinct disadvantage because of various physiological limitations.⁵

Very High Growth Rate

- Intrauterine weight gain 16 to 17 g/kg body weight per day (approx. 3 folds from 28th to 40th week). Gains around 20 cm in length
- Brain size increases three and half times.

Very Low Nutrient Stores

- Low fat and glycogen stores
- Lack of body building nutrients
- From 25 to 40th week body accumulates 20,000 mg of calcium.

Immature Organs

Gastrointestinal Tract

- Increased GI tract permeability leading to intestinal inflammation and injury
- Delayed gut colonization with Bifido bacteria.

Lack of Digestion and Absorption

- Smaller stomach capacity
- Delayed emptying of gastric content
- Low levels of intestinal lactase, lactose digestion is poor
- Low levels of pancreatic lipase and bile salts results in poor fat absorption.

Renal Function

- Low glomerular filtration rate
- Acidosis occurs early
- Poor urine concentration. Infant gets dehydrated readily.

Central Nervous System

- Uncoordinated sucking and swallowing
- Regurgitation and aspiration.

Respiratory System

- Resuscitation problems
- Hyaline membrane disease
- Vulnerable to chronic pulmonary insufficiency due to bronchopulmonary dysplasia.

The current concept of nutrition of very low birth weight infants is to provide aggressive nutrition as the ill effects of undernutrition are well established. During the acute phase of the disease, aim is to avoid catabolism and not growth. This is difficult in VLBW infants due to higher requirements, poor stores and reduced intake. After stabilization during the growing period, aim is to approximate *in utero* growth rate of a normal fetus of the same gestation with no functional impairment. There should be positive energy balance to sustain growth. Inadequate nutrition leads to poor postnatal growth which ultimately leads to impaired neurocognitive development.

Sources of nutrient recommendations for preterm infants include the American Academy of Pediatrics Committee on Nutrition, the European Society of Paediatric Gastroenterology Hepatology and Nutrition Committee on Nutrition (ESPGAN-CON), National Neonatology Forum⁶ and the reasonable ranges of nutrient intakes published by Tsang et al.⁷

CHOICE OF MILK FOR FEEDING PRETERM BABIES

The different choices of milk for preterm are breast milk, fortified human milk and preterm specialized formula milk. Breast milk remains the choice of feeding of all neonates. Breast milk confers significant advantage for

protection against infection and NEC in preterm infants. Breast milk in sufficient volume has been shown to achieve a desirable weight gain in preterm infants. Breast milk provides ideal whey casein ratio (60:40) and whey protein is easily digestible, contains long chain polyunsaturated fatty acid (LCPUFA) which is important for brain and retinal growth. It also contains oligosaccharides which help in host defense. The neurodevelopmental outcome also has been reported to be better with breastfeeding. However feeding exclusive breast milk to a preterm baby <32 weeks may have certain disadvantages. Though preterm milk initially contains higher protein but the protein content gradually declines over next 3 to 4 postnatal weeks. It also contains inadequate amounts of calcium and phosphate. A growing preterm needs higher protein, calorie, calcium, phosphate than can be provided by breast milk alone. Hence, the preterm babies may need additional supplements during the catch up growth if weight gain is not adequate. Table 1 shows recommended nutrient intakes as per ESPGHAN 2009.

NUTRITIONAL REQUIREMENTS OF PRETERM INFANTS FOR SOME IMPORTANT NUTRIENTS⁵

Energy

Recommendations for energy intake are based on growth and nutrient retention similar to intrauterine references. The recommendations should achieve not only weight gain but also body composition similar to intrauterine growth standards. It is also emphasized that rapid infant weight gain in term infants may be associated with adverse outcomes. Synthesis of new tissue is strongly affected by the intake of protein and other nutrients; thus, achieving an adequate energy to protein ratio is as important as providing adequate energy intake.

Based on intrauterine standards, a reasonable range of energy intake for healthy growing preterm infants with adequate protein intake is 110 to 135 kcal/ kg/ day. Increasing energy intake may not be appropriate for infants whose growth appears inadequate (without evidence of fat malabsorption) because it is more likely that other nutrients (e.g. protein) are rate limiting.

Proteins

Proteins are the main building blocks and a suboptimal intake of protein, energy, and other nutrients may lead to lower cognitive achievements. Protein accretion has been estimated at approximately 1.7 gm/kg/day for fetuses throughout the second half of gestation but is lower at the end of gestation. Obligatory protein losses are at least 0.7 gm/ kg/ day but may be higher if nitrogen losses from skin and breath could be measured. Based on the protein needs and nitrogen utilization, the protein intake

Table 1: Recommended intakes for macro- and micronutrients expressed per mg kg⁻¹ day⁻¹ and per 100 kcal unless otherwise denoted

<i>Min–Max</i>	<i>Per⁻¹ day⁻¹</i>	<i>per 100 kcal</i>
Fluid, mL	135-200	
Energy, kcal	110-135	
Protein, g <1kg body weight	4.0-4.5	3.6-4.1
Protein, g 1-1.8 kg body weight	3.5-4.0	3.2-3.6
Lipids, g (of which MCT <40%)	4.8-6.6	4.4-6.0
Linolenic acid, mg	385-1540	350-1400
α-linolenic acid, mg	>55 (0.9% of fatty acids)	>50
DHA, mg	12-30	11-27
AA, mg	18-42	16-39
Carbohydrate, g	11.6-13.2	10.5-12
Sodium, mg	69-115	63-105
Potassium, mg	66-132	60-120
Chloride, mg	105-177	95-161
Calcium salt, mg	120-140	110-130
Phosphate, mg	60-90	55-80
Magnesium, mg	8-15	7.5-13.6
Iron, mg	2-3	1.8-2.7
Zinc, mg	1.1-2.0	1.0-1.8
Copper, μg	100-132	90-120
Selenium, μg	5-10	4.5-9
Manganese, μg	≤27.5	6.3-25
Fluoride, μg	1.5-60	1.4-55
Iodine, μg	11-55	10-50
Chromium, μg	30-1230	27-1120
Molybdenum, μg	0.3-5	0.27-4.5
Thiamine, μg	140-300	125-275
Riboflavin, μg	200-400	180-365
Niacin, μg	380-5500	345-5000
Pantothenic acid, mg	0.33-2.1	0.3-1.9
Pyridoxine, μg	45-300	41-273
Cobalamin, μg	0.1-0.77	0.08-0.7
Folic acid, μg	35-100	32-90
L-ascorbic acid, mg	11-46	10-42
Biotin, μg	1.7-16.5	1.5-15
Vitamin A, μg RE, 1 μg~3.33 IU	400-1000	360-740
Vitamin D, IU/day	800-1000	
Vitamin E, mg (α-tocopherol equivalents)	2.2-11	2-10
Vitamin K ₁ , μg	4.4-28	4-25
Nucleotides, mg		≤5
Choline, mg	8-55	7-50
Inositol, mg	4.4-53	4-48

should be at least 3.0 gm/ kg/ day. Intrauterine weight gain can be matched at protein intakes <3 to 3.5 gm/ kg/ day accompanied by a high energy intake, but body fat percentage will then be much higher than observed in the fetus. Intakes in the range of 3 to 4.5 gm/ kg/ day will achieve acceptable plasma albumin and transthyretin concentrations. Some excess of protein intake over requirements was not shown to cause detrimental effects in preterms, but a small deficit will impair growth. ESPGHAN recommends 4.0 to 4.5 gm/ kg/ day protein intake for infants up to 1000 gm, and 3.5 to 4.0 gm/ kg/ day for infants from 1000 to 1800 gm. This will meet the needs of most preterm infants.

Lipids

Apart from providing much of its energy needs, dietary lipids also provide the preterm infants with essential polyunsaturated fatty acids, and lipid-soluble vitamins. Long chain polyunsaturated fatty acids (LCPUFAs) are important for cell membrane functions and the formation of bioactive eicosanoids. Brain grey matter and the retina are particularly rich in long-chain polyunsaturated fatty acids.

Assuming a daily intrauterine fat deposition of 3 g/kg, 10 to 40 percent loss from fat malabsorption, and 15 percent loss from unavoidable oxidation, and conversion of absorbed triglyceride to deposited triglyceride in tissue, a minimal dietary fat intake of 4.8 gm/ kg/ day is suggested.

Although some infants with restricted fluid and feed intakes may need high fat intakes to meet energy needs, for most preterm infants a reasonable range of fat intake is 4.8 to 6.6 gm/ kg/ day or 4.4 to 6.0 gm/100 kcal (40–55% of energy intake). The medium-chain triglyceride content in preterm formula, if added, should be in the range of up to 40 percent of the total fat content.

The recommended intakes are for DHA (docosahexaenoic acid) 12-30 mg/kg/day and for AA (arachidonic acid) 18-42 mg/kg/day with a ratio of AA:DHA::1-2:1. Eicosapentaenoic acid competes with AA and the levels are low in human milk; hence its supply should not exceed 30 percent of DHA supply.

Calcium

Calcium absorption depends on calcium and vitamin D intakes, and that calcium retention is additionally related to absorbed phosphorus. Various studies suggest that calcium retention ranging between 60 and 90 mg/ kg/ day decreases the risk of fractures, diminishes the clinical symptoms of osteopenia, and ensures appropriate mineralization in very-low-birth-weight (VLBW) infants. Thus, a calcium intake of 120 to 140 mg/ kg/ day with an absorption rate of 50 to 65 percent will lead to calcium retention of 60 to 90 mg/ kg/ day.

Phosphorus and Calcium to Phosphorus Ratio

- The calcium to phosphorus ratio may be an important determinant of calcium absorption and retention. The present recommendation for preterm formula is calcium to phosphorus ratio close to 2:1, but ideally this should be adapted taking into account nitrogen retention as well as bioavailability of the calcium salt. Considering a nitrogen retention ranging from 350 to 450 mg/ kg/ day and calcium retention from 60 to 90 mg/ kg/ day, the adequate phosphorus intake represents 65 to 90 mg/ kg/ day of a highly absorbable phosphate source (90%) with a calcium to phosphorus ratio between 1.5 and 2.0. Individual needs can be determined by measuring spot urinary calcium <6 mg/kg/d and urinary excretion of P >4 mg/ kg/ d.

Vitamin D

Vitamin D is important for supporting a large number of physiological processes such as neuromuscular function and bone mineralization. The requirements of vitamin D for optimal growth in VLBW and extremely-low-birth-weight infants are still matters for discussion. Studies have suggested a vitamin D intake of 800 to 1500 IU/ day which is necessary to reach a circulating 25(OH)D concentration above 75 nmol/ L. ESPGHAN recommends a vitamin D intake of 800 to 1000 IU/ day (and not per kilogram) during the first months of life.

Iron

Iron is essential for brain development, and many observational studies have shown an association between iron deficiency anemia and poor neurodevelopment in infants. Excessive iron supplementation of infants on the other hand may lead to increased risk of infection, poor growth, and disturbed absorption or metabolism of other minerals. Thus, one must prevent not only iron deficiency but also iron overload.

ESPGHAN recommends an iron intake of 2 to 3 mg/ kg/ day, given as a separate iron supplement, in preterm formula or in fortified human milk. Iron supplementation should be started at 2 to 6 weeks of age (2-4 weeks in extremely low birth weight infants). Infants who receive erythropoietin treatment and infants who have had significant, uncompensated blood losses may initially need a higher dose, requiring a separate iron supplement in addition to preterm formula or fortified human milk. Enteral iron doses >5 mg/kg/day should be avoided in preterm infants because of the possible risk of retinopathy of prematurity. Iron supplementation should be delayed in infants who have received multiple blood transfusions and have high serum ferritin concentrations. Iron supplementation should be continued after discharge, at least until 6 to 12 months of age depending on diet.

Table 2: Composition of various feeding options available for preterm infants per 100 ml of feed

<i>Per 100 ml</i>	<i>EBM</i>	<i>EBM and Lactodex HMF</i>	<i>EBM and Similac HMF</i>	<i>Lactodex</i>	<i>Dexolac</i>	<i>Enfamil</i>
Energy (Kcal)	67	82	81	80	68	68
Protein (gm)	1.1	1.5	2.1	2.16	1.7	1.4
Fat (gm)	3.5	3.6	3.9	4	3.5	3.7
Vitamin A (IU)	48	288	668	240	582	256
Vitamin D (IU)	8	84	128	72	69.6	54.4
Calcium (mg)	25.3	125	142	136	112.4	52
Phosphorus (mg)	14.5	64.5	81.5	68	56	29
Iron (mg)	0.09	0.09	0.44	1.9	1.23	1.22

Which milk is the best milk for preterms?

As evident from the above discussion, there are certain increased requirements for these preterm neonates and hence fortified human milk is the best available option to meet the nutritional requirements of preterm babies. Alternatively, a preterm formula would be required for this group of preterm neonates (Table 2).

Feeding Protocol for Preterm Babies, < 32 weeks and < 1800 gram

Choice of milk

First choice milk is maternal EBM (with HMF supplementation to 24 calories/30 ml when the baby is tolerating 100 ml/kg/day). *Second choice milk* would be Preterm formula.

Initiation of feeding

- Well babies
 - >30 weeks can be started immediately on total milk feeds.
 - <30 weeks: start feeds on D1 along with parenteral nutrition
 - <28 weeks: minimal enteral feeds on Day 2 or 3.
- Sick babies
 - >28 weeks, start enteral feeds when it is felt clinically appropriate.

Progression of feeds

- Well baby, no risk factors, baby tolerating feeds: Increase by 20 – 30 ml/ kg/ day
- Slow progression if baby shows features of feed intolerance
- In defining the rate of increase the following needs to be considered:
 - Gestation and weight of the baby
 - How sick the baby has been
 - How well the milk is being tolerated (vomits or large residuals)
 - Any abdominal signs, e.g. distention.

Final feed volume

Final feed needs to be individualized in each baby. A weight gain 15g/ kg/ day (range 10-25 g/kg/ day) should be targeted which can be achieved at a volume of around 180 ml/ kg/ day.

Nutritional assessment of the enterally fed premature infant

Component measured	Frequency
Fluid intake (ml/ kg/ day)	Daily
Nutrient intake	Daily
Energy intake (Kcal)	
Protein (g)	
Specific nutrient (unit)	
Anthropometry	
Body weight (g)	Same time each day
Length (cm)	Weekly
Head circumference (cm)	Weekly
Biochemical monitoring	
Hemoglobin, hematocrit	Weekly
Serum electrolytes	Twice weekly, then every 2 weeks
Calcium, phosphorus	Twice weekly, then every 2 weeks
Alkaline phosphatase	Twice weekly, then every 2 weeks
Albumin, BUN	Twice weekly, then every 2 weeks
Other assessments	
Renal USG	At 2 months of age (for nephrocalcinosis)

A daily weight gain of 1 to 1.5 percent of birth weight, length gain of approximately 0.9 cm/week and increase in head circumference of 0.7 to 0.9 cm/week are ideal desired targets.

Postdischarge Feeding

Most of the follow-up studies of VLBW and ELBW show that at discharge they are <10th centile and this growth failure continues in next few years. Though the current

feeding policies concentrate only on feeding practices during hospital stay, there is a need to have adequate calorie, protein and other mineral intake after discharge also. Policy of aggressive nutrition for preterm VLBW and ELBW infants should continue beyond discharge to improve growth during early infancy and childhood.

Practical guidelines at discharge

- For babies on direct human milk: continue calcium/phosphorus, iron and multivitamin drops and follow up on the growth chart. If continue to follow the target percentile; continue. If starts falling the percentile, add HMF.
- For babies on human milk but not direct feeds: <1800 gm—discharged on HMF, MV drops/iron. Calcium/phosphorus supplementation not required.
- Alternative is preterm special formulae.

GROWTH CHARTING

These babies should be followed on intrauterine growth charts (e.g. Fenton's charts) till 40 weeks of gestation and then subsequently on WHO growth standard charts.

CONCLUSION

There is ample evidence that most of the VLBW and ELBW infants suffer significant postnatal malnutrition. They remain <10th percentile for weight at discharge. Hence, one should adopt the policy of aggressive enteral nutrition from very early in life. As parenteral nutrition is

a difficult proposition in our country, one should attempt oral feeding as soon as the baby is stable. For high-risk babies at least minimal enteral nutrition should continue till the baby is ready for full feeds. Breastfed babies should get additional supplements with protein, minerals and vitamins which should continue even after discharge.

CHAPTER 6

Acid-base Balance

Manoj Modi, Siddarth Ramji

INTRODUCTION

A normal acid-base homeostasis is essential for intact functioning of all enzymatic processes and hence all organ systems of body. Blood gases are the basis for diagnosis and management of infants with cardiorespiratory diseases, metabolic disorders and other systemic illnesses. By integrating information derived from blood gas and clinical history, healthcare provider can accurately assess an infant's current condition and can take the appropriate steps to correct the imbalance so as to improve outcomes.

PHYSIOLOGY OF ACID-BASE BALANCE

In health, the normal range of hydrogen ions in ECF is 35 to 45 nmol/L. In clinical practice this is reflected as pH, which is negative logarithm of hydrogen ion concentration.

$$\text{pH} = -\log [\text{H}^+]$$

The corresponding pH value for normal range of hydrogen ion concentration is 7.35 to 7.45. The pH will be lower than 7.35, if hydrogen ion concentration is increased and will be higher than 7.45 if hydrogen ion concentration is decreased. This is called acidemia and alkalemia, respectively.

Acid load comes primarily from cellular respiration as carbon dioxide via carbonic acid (15,000–20,000 mmol H^+ /day) and to a lesser extent from the metabolism of fats and proteins (50 mmol/day). The concentration of hydrogen ions in blood plasma is very tightly regulated. The main organ systems that maintain pH in the normal range are respiratory system and kidneys. Some of these systems respond immediately to sudden alterations in hydrogen ion concentrations, whereas others respond more slowly.

Defence of normal body pH is achieved through the three following basic mechanisms:

- Respiratory control of the partial pressure of carbon dioxide in arterial blood (pCO_2) by the respiratory center, which is a rapid and powerful compensatory system. This regulates pH by changing rate of alveolar ventilation. The higher the concentration of $[\text{H}^+]$, the more CO_2 (which is a volatile acid) is expired from the lungs, and eventually pH will be normalized.
- Renal bicarbonate control and excretion of metabolic acids (nonvolatile acids). The kidneys are slower to compensate, but renal physiology has several powerful mechanisms to control pH by the excretion of excess acid or base. In responses to acidosis, tubular cells reabsorb more bicarbonate from the tubular fluid, collecting duct cells secrete more hydrogen and generate more bicarbonate, and ammoniogenesis leads to increased formation of the NH_3 buffer. In responses to alkalosis, the kidney may excrete more bicarbonate by decreasing hydrogen ion secretion from the tubular epithelial cells, and lowering rates of glutamine metabolism and ammonia excretion.
- Buffering by intracellular and extracellular anions and proteins, which minimizes acute changes. Buffer is a substance that has ability to bind or release hydrogen ion and hence can minimize changes in pH when acid or base is added to the system. The extracellular buffers, which include the bicarbonate-carbonic acid system, phosphate, and plasma proteins, act rapidly to return the extracellular pH toward normal. The intracellular buffers, which include hemoglobin, organic phosphates and bone apatite, act more slowly.

The most important extracellular buffer is plasma bicarbonate-carbonic acid buffer system, in which the acid component (carbonic acid $[\text{H}_2\text{CO}_3]$) is regulated by the lungs and the base component (bicarbonate $[\text{HCO}_3^-]$) is regulated by the kidneys.

The traditional approach to acid-base control centers round the Henderson-Hasselbalch equation, which describes the carbonic acid buffer system, fundamental to respiratory and renal control of pH. The reaction of

carbon dioxide with water forms carbonic acid, which dissociates to form bicarbonate and H^+ ions:

The buffer equation is

If hydrogen ion concentration increases for any reason, hydrogen combines with HCO_3^- , driving the buffer reaction toward greater production of H_2CO_3 and hence CO_2 . Increased CO_2 stimulates brain respiratory center, leading to increased alveolar ventilation and removal of CO_2 and normalization of pH. Similar compensation (in reverse direction) occurs in response to a decrease in hydrogen ion concentration with restoration of pH.

The Henderson-Hasselbalch equation can be modified as follows:

If by the law of mass action:

$$[H^+][HCO_3^-]/[H_2CO_3] = k \text{ (constant)}$$

Then by rearranging and taking logs of both sides:

$$pH = pK_a + \log ([HCO_3^-]/[0.03 \times pCO_2 \text{ mm Hg}])$$

where the pK_a value at $37^\circ C$ is 6.1.

From this equation, pH can be defined as the ratio of bicarbonate to carbon dioxide. Therefore, alterations in acid-base result from either changes in CO_2 (respiratory) or changes in HCO_3^- (metabolic) and compensatory mechanisms exist to maintain this ratio (normally 20:1).

Interpreting a Blood Gas Report

Usual blood gas report contains following parameters:

- pH
- PCO_2
- PO_2
- HCO_3^- (actual)
- HCO_3^- (standard)
- Base excess (actual)
- Base excess (standard)

Blood gas analyzers directly measure pH, PCO_2 and PO_2 . Bicarbonate is calculated from modified Henderson-Hasselbalch equation, while standardized HCO_3^- and base excess are derived from computerized nomograms.

The concepts of standard bicarbonate and standard base excess have been introduced to assist with quantifying the metabolic derangement. Standard bicarbonate is the calculated bicarbonate value that would be present if the blood sample was adjusted to a pCO_2 of 40 mm Hg and therefore removes the respiratory component of the acid-base abnormality to reveal any metabolic derangement. Standard base excess or deficit quantifies the amount of acid in mmol/liter that must be added or subtracted from the same blood sample to regain a normal pH at a pCO_2 of 40 mm Hg.

Normal Value of Blood Gas Parameters

pH = 7.35 to 7.45

pCO_2 = 40 mm

pO_2 = 50 to 80 mm

HCO_3^- = 24 mEq/L

Base excess = \pm 5 mEq/L

Acidosis = pH < 7.35

Alkalosis = pH > 7.45

Developmental Aspects of Acid-base Physiology

Maturation of renal functions continue during neonatal period and early infancy. The relative immaturity of the kidney, which is more pronounced in the preterm infant, affects acid-base status.¹

During initial 24 to 48 hour of life, acid-base balance is influenced by the degree of perinatal stress and environmental factors such as temperature and diet. These factors modify the blood gas parameters. Median umbilical artery values, with the 2.5th percentile value in parentheses, are pH 7.26 (7.10) and base excess -4 mmol/L (-12 mmol/L).²⁻⁴ Values for pH, PCO_2 , and base excess also vary with differences in sampling technique. Preanalytical error can be introduced if the cord is not clamped immediately, there is an excess quantity of heparin in relation to the amount of blood collected, air is present in the syringe, or the sample is kept at room temperature for longer than 15 minutes.⁵

Between 7 and 21 days of life, neonates are in a state of mild metabolic acidosis (pH 7.25-7.35, HCO_3^- 19-22 mEq/L). In some infants, blood pH drops below 7.25 or base deficit exceeds 8 mEq/L.⁶ Many factors cause metabolic acidosis in neonates. The threshold for bicarbonate reabsorption in proximal tubules is lower in neonates, especially preterm infants. In addition, low GFR, particularly in preterm neonates, decreases the availability of phosphates and other buffers. Tubular immaturity results in reduced tubular secretory surface for organic acid secretion. Renal control of acid-base homeostasis doesn't reach adult levels until approximately 2 years age.

CLASSIFICATION OF ACID-BASE DISORDERS

- *Metabolic acidosis*: Accumulation of abnormal acid in body or loss of buffer base.
- *Metabolic alkalosis*: Accumulation of abnormal base in body or loss of acid.
- *Respiratory acidosis*: Increase in pCO_2 in blood.
- *Respiratory alkalosis*: Decrease in pCO_2 in blood.

Steps in Interpreting Blood Gas

A blood gas report should be read and interpreted in following order:

- Look for primary disorder (acidosis/alkalosis) (Fig. 1)
- Look for possible explanation for the disorder (respiratory/metabolic)
- Look for compensation

Table 1: Compensatory responses to primary acid-base disorders

Primary disorder	Compensation	Rate of compensation
Metabolic acidosis	$\downarrow \text{PCO}_2$	For every 1 mEq fall in HCO_3^- , PCO_2 fall by 1-1.5
Metabolic alkalosis	$\uparrow \text{PCO}_2$	For every 1 mEq rise in HCO_3^- , PCO_2 rise by 0.5-1
Acute respiratory acidosis (<12-24 hour)	$\uparrow \text{HCO}_3^-$	For every 10 rise in PCO_2 , HCO_3^- rise by 1 mEq
Chronic respiratory acidosis (3-5 days)	$\uparrow \text{HCO}_3^-$	For every 10 rise in PCO_2 , HCO_3^- rise by 4 mEq
Acute respiratory alkalosis (<12 hours)	$\downarrow \text{HCO}_3^-$	For every 10 fall in PCO_2 , HCO_3^- fall by 1-3 mEq
Chronic respiratory alkalosis (1-2 days)	$\downarrow \text{HCO}_3^-$	For every 10 fall in PCO_2 , HCO_3^- fall by 2-5 mEq

Modified from Brewer ED: Disorder of acid-base balance. *Pediatr Clin North Am* 1990;37:430-47

Fig. 1: Acid-base nomogram showing 95% confidence limits for compensatory responses to primary acid-base disorders. (From Cogan MG, Rector FC Jr' Acid-base disorders. In Brenner BM, Rector FC Jr [Eds]: *The Kidney*. Philadelphia, WB Saunders, 1986, p 462)

Step 1

Look for primary disorder. It can be acidosis (if $\text{pH} < 7.35$) or alkalosis (if $\text{pH} > 7.45$)

Step 2

Look for possible explanation for the disorder.

- If acidosis is there, then it could be either metabolic acidosis ($\text{HCO}_3^- < 24$) or respiratory acidosis ($\text{PCO}_2 > 40$) or both.
- If alkalosis is there, then it could be either metabolic alkalosis ($\text{HCO}_3^- > 24$) or respiratory alkalosis ($\text{PCO}_2 < 40$) or both.

Step 3

Look for compensation (Table 1):

- For primary metabolic acidosis, there will be compensatory respiratory alkalosis; for primary metabolic alkalosis, there will be compensatory respiratory acidosis.
- For primary respiratory acidosis, there will be compensatory metabolic alkalosis; and for primary respiratory alkalosis, there will be compensatory metabolic acidosis.
- Respiratory compensation of metabolic disturbances is fast and occurs within minutes to hours where as full

metabolic compensation of primary respiratory disorders takes days. Hence respiratory acidosis and alkalosis are subdivided into acute and chronic based on duration of illness and degree of compensation.

- Compensation is obligatory, not optional.
- Compensation is never complete. That means pH is near normal (close to 7.35) but never completely normalized or overshoot (7.4 or above) by compensatory mechanism itself.
- If expected compensation does not occur, then mixed disorder (respiratory + metabolic) should be suspected.
- Expected compensation can be derived from either by acid-base nomogram by Cogan (Fig. 1) or Table 1.

METABOLIC ACIDOSIS (FIG. 1)

Metabolic acidosis is a common problem, particularly in the critically ill neonate. Metabolic acidosis occurs when the drop in pH is caused by the accumulation of acid other than H_2CO_3 by ECF resulting in loss of available HCO_3^- or by direct loss of HCO_3^- from body fluids. Metabolic acidosis is categorized into normal anion gap or increased anion gap metabolic acidosis. Anion gap reflects the unmeasured anion in body. Anion gap is calculated by following equation:

Anion gap = $\text{Na} + \text{K} - \text{Cl} - \text{HCO}_3$ (Normal value 12 ± 4 mEq/L)

Causes of Metabolic Acidosis

Increased Anion Gap

- Secondary lactic acidosis (hypoxia, ischemia, shock, dehydration, hypothermia, sepsis, etc.)
- Primary lactic acidemia
- Organic acidemia
- Renal failure
- Late metabolic acidosis
- Adrenal insufficiency, CAH
- Toxins (benzyl alcohol)
- Diabetic ketoacidosis.

Normal Anion Gap

- Renal bicarb wasting due to immaturity
- Renal tubular acidosis
- Carbonic anhydrase inhibitors
- Gastrointestinal bicarb loss (diarrhea, ileostomy drainage, fistula)
- Dilutional (rapid ECF expansion with non- HCO_3 fluid in hypovolemic infant), excessive chloride in IV fluids, aldosterone deficiency.

Evaluation

The etiology of metabolic acidosis is often apparent from history and physical examination. Basic laboratory tests in an infant with metabolic acidosis include BUN, creatinine, serum electrolytes, blood sugar, and lactate and urine analysis. Blood gas report and serum electrolytes will differentiate normal and increased anion gap acidosis.

In acutely sick neonate who had incurred hypoxia or hypoperfusion, secondary lactic acidosis is most common differential diagnosis for increased anion gap acidosis. An elevated BUN, Creatinine are present in renal insufficiency, whereas elevated BUN/Cr ratio ($>20:1$) supports a diagnosis of prerenal azotemia and associated hypoperfusion induced lactic acidosis. Unexplained increased anion gap metabolic acidosis with or without hypoglycaemia should prompt a work-up for inborn errors of metabolism or endocrinopathy (adrenal insufficiency, CAH).

A metabolic acidosis with normal anion gap is usually due to intestinal content losses or renal abnormalities. If there is no history of GI losses, probable etiology of acidosis is renal. A urine pH >6.5 in presence of metabolic acidosis supports the diagnosis of RTA or prematurity associated bicarb wasting.

Further investigations can be done based on findings of initial work-up.

Management

Treatment of secondary lactic acidosis is usually supportive with correction of hypoxia/hypoperfusion, restoration

of hydration, and treatment of sepsis. Supportive therapy will rapidly correct the acidosis. Bicarb therapy is not advocated routinely. However, if pH is <7.2 , (particularly despite restoration of oxygenation/perfusion), bicarb administration can be considered along with other supportive measures.

Amount of bicarb is calculated by following formula:

Bicarb deficit (mEq) = $0.3 \times \text{Desired} - \text{standard bicarb}$

Give calculated bicarb as slow infusion (1:1 diluted) over 2-4 hours (no more than 1 mEq/kg/hr). Most clinicians would use half of the calculated dose for initial therapy to avoid overcorrection of metabolic acidosis. Subsequent doses of sodium bicarbonate are then based on the results of further blood gas measurements.

In case of unexpected/refractory increased anion gap metabolic acidosis, possibility of inborn errors should be considered and appropriate evaluation should be done. Do blood lactate, ammonia, urine ketone, blood sugars, urine reducing substance, plasma and urine organic acids, blood TMS, etc. to establish the cause. Restrict/modify dietary protein intake. Give bicarb correction if pH is <7.2 . As vitamins are cofactors in various enzymatic reactions, vitamin cocktail therapy is used empirically in suspected inborn errors of metabolism. In refractory conditions, peritoneal dialysis may be helpful.

Normal anion gap acidosis is usually due to renal immaturity or renal tubular acidosis. Treatment is bicarb supplementation as required to maintain pH in acceptable range (7.25–7.35). Requirement for bicarb supplementation may decrease gradually as renal functions improve, warranting periodic assessment.

METABOLIC ALKALOSIS

Metabolic alkalosis is characterized by alkalemia due to a primary increase in the extracellular HCO_3^- concentration. In newborn, metabolic alkalosis occurs when there is a loss of H^+ or due to gain of HCO_3^- or due to depletion of extracellular volume with the loss of more chloride than HCO_3^- .

Conventionally, etiology of metabolic alkalosis is divided into two categories: Chloride responsive (urinary chloride <15 mEq/L) or chloride resistant (urinary chloride >15 mEq/L).

Chloride responsive (urine Chloride <15 mEq/L):

- Gastric losses (nasogastric suction, persistent vomiting)
- Diuretic therapy
- Chloride losing diarrhea
- Cystic fibrosis
- Posthypercapnia

Chloride resistance (urine Chloride >15 mEq/L)

High Blood Pressure

- Hyperaldosteronism
- Congenital adrenal hyperplasia (17 α -hydroxylase def., 11 β -hydroxylase def, 11 β -HSD)

Normal Blood Pressure

- Bicarb administration, blood products
- Hypokalemia
- Bartter syndrome
- Gitelman syndrome

In loss of gastric content conditions, HCl loss is mechanism of generation of metabolic alkalosis, which is further maintained through volume depletion. Volume depletion interferes with urinary loss of bicarbonate through following mechanisms. First there is reduction of GFR so less bicarbonate is filtered. Second, volume depletion increases reabsorption of sodium and bicarbonate from proximal tubules mediated by angiotensin II. Third, increased aldosterone, in response to volume depletion, increases bicarbonate reabsorption and H^+ secretion in collecting ducts.

Chronic diuretic therapy, which may be a part of management of chronic lung disease, posthemorrhagic hydrocephalus or congestive cardiac failure, induces volume depletion and hence metabolic alkalosis through the same mechanisms.

Posthypercapnic metabolic alkalosis occurs after sudden correction of chronic respiratory acidosis. This is typically seen after placing infant with chronic respiratory acidosis on ventilator. During chronic respiratory acidosis, appropriate renal compensation is elevation of bicarbonate, which maintains pH close to 7.35. On sudden resolution of respiratory acidosis through ventilation of these infants, elevated bicarbonate leaves behind the metabolic alkalosis, which is spontaneously corrected gradually, unless patient in volume depleted in addition.

Chlorideresistant metabolic alkalosis is more often an iatrogenic condition, when there is chronic excessive administration of soda-bicarbonate, lactate, citrate or acetate in intravenous fluids or blood products. Metabolic alkalosis in these situations resolves readily, once HCO_3^- administration is discontinued, unless urine output is very low. Other causes of high urinary chloride metabolic alkalosis can be further differentiated based on normal or high blood pressure and confirmation can be done by appropriate laboratory tests.

Evaluation

A possible diagnosis can be ascertained by thorough history and clinical examination, supported by common laboratory tests, such as serum electrolytes and urine chloride. Assess for possibility of ECF contraction, diuretic therapy or bicarb administration as cause of metabolic alkalosis.

Management

Approach to therapy of metabolic alkalosis depends on the severity of alkalosis and underlying etiology.

In mild metabolic alkalosis induced by diuretic therapy, no intervention may be required, though in severe

alkalosis, dose may be reduced or drug discontinued. Adequate potassium supplementation or addition of potassium sparing diuretic is also helpful in diuretic induced metabolic alkalosis.

In settings of nasogastric suction, suctioning may be reduced or stopped. Alternatively, addition of proton pump inhibitor may be considered, where suctioning cannot be discontinued and alkalosis is severe.

Many infants with metabolic alkalosis have volume depletion as etiology for the disorder. In this situation, administration of sufficient sodium chloride and potassium to correct the volume deficit and potassium deficit is necessary for resolution of metabolic alkalosis. This option may not be appropriate in conditions where volume repletion is contraindicated (chronic lung disease, congestive cardiac failure, etc.).

In metabolic alkalosis due to hyperaldosteronism state, treatment focuses on eliminating the excess aldosterone effect. Glucocorticoid-remediable aldosteronism, 17α -hydroxylase deficiency and 11β -hydroxylase deficiency respond to administration of glucocorticoids. The mineralocorticoid effect of cortisol in 11β -HSD deficiency can be decreased by using spironolactone.

In children with Bartter syndrome and Gitelman syndrome, therapy includes oral potassium supplementation and potassium sparing diuretics.

In post hypercapnic metabolic alkalosis, management involves reducing ventilatory settings so as to keep pH in acceptable range. Metabolic alkalosis will resolve spontaneously over 3-4 days.

RESPIRATORY ACIDOSIS

Respiratory acidosis is fall in pH due to an inappropriate increase in blood CO_2 .

Causes

- CNS depression
 - HIE, IVH, PVL
 - Sepsis/meningitis/encephalitis
 - Structural brain malformations, brain stem dysfunction
 - Central apnea, Ondine curse
 - *Drugs*: Phenobarb, morphine, midazolam, etc.
- Disorders of spinal cord, peripheral nerve, neuromuscular junction, muscle
 - Diaphragmatic paralysis
 - Spinal cord injury
 - Spinal muscular atrophies
 - Myasthenia
 - Botulism
 - Muscular dystrophies
 - Drugs/hypokalemia
- Upper airways diseases
 - Obstructive apneas

- Micrognathia
- Vocal cord paralysis
- Extrinsic compression
- Pulmonary disease
 - Pneumonia, sepsis
 - Pneumothorax, effusions, pulmonary edema
 - MAS, pulmonary hemorrhage, HMD, BPD
 - Pulmonary hypoplasia

Diagnosis

Diagnosis of respiratory acidosis is straight forward by looking at gas parameters. Establishing cause of respiratory acidosis requires thorough history and physical examination, chest X-ray and other investigation.

Treatment

Treatment is directed to the underlying cause and providing adequate ventilatory support, if required. Care should be exercised in ventilator management of respiratory acidosis, as overenthusiastic ventilation will lead to lung injury. A blood PCO_2 up to 60 mm may be acceptable as long as pH remains above 7.2 to 7.25 (permissive hypercapnia) and work of breathing is not very high. Gradually metabolic compensation will take place, with restoration of pH.

Particular attention should be paid in management of chronic respiratory acidosis. In chronic respiratory acidosis, there might have been appropriate metabolic compensation. Overenthusiastic ventilation of such patient will lead to rapid lowering of pCO_2 with residual metabolic alkalosis. This condition should be anticipated and ventilatory support should be appropriate so as to avoid post hypercapnic metabolic alkalosis.

RESPIRATORY ALKALOSIS

When a primary decrease in an increase in arterial pH beyond 7.45, respiratory alkalosis develops.

Causes

- Central nervous system disorders (asphyxia, hyperammonia, etc.)
- Pain, fever, sepsis
- Retained lung fluid, mild aspiration pneumonia
- Iatrogenic: Excessive ventilatory support
- Erroneous: contamination with air bubble in blood sample

Diagnosis

Diagnosis of cause is ascertained by history and physical examination. A common scenario is contamination of blood gas sample with air bubble. In this situation, pCO_2 is unexpectedly low and pO_2 is unexpectedly high (usually >100). In normal circumstances, $\text{pO}_2 >80$ is unusual in a neonate breathing at room air. Even in ventilated neonate, pO_2 above 100 is unusual, if SPO_2 is in target range (88–92%). Hence, we find pCO_2 too low and pO_2 too high (which is not explainable by clinical settings), consider possibility of contamination by air bubble and repeat the blood gas.

Management

Management is conservative. Treat underlying disorder (pain, fever). Decrease ventilatory settings if ventilated. Mild sedation can be attempted in case of severe central hyperventilation

CHAPTER 7

Hemodynamic Assessment in the Newborn

Samir Gupta, Sunil Sinha

INTRODUCTION

Cardiorespiratory assessment and management of the newborn is essential for the provision of neonatal intensive care. Over the last decade, with the advances in the microprocessor technology there are now a variety of modalities available for respiratory support of the newborn. Additionally, clinicians have realised the usefulness of hemodynamic assessment in the management of sick and very premature newborn infants. As oxygenation and carbon dioxide removal depends on adequate ventilation and perfusion, changes in ventilation can affect perfusion and vice versa. Lung and organ perfusion depends on intact cardiac function and hemodynamics, hence understanding of the later is crucial for appropriate management of sick newborns. Traditionally hemodynamic assessment utilized clinical signs with limited objectivity but the technological advances have provided new tools to compliment clinical assessment and quantify the measurements.

This chapter focuses on hemodynamic assessment techniques utilized on the Neonatal Intensive Care Unit with a special emphasis on the use of point of care echocardiography.

CHARACTERISTICS OF HEMODYNAMICS IN THE NEWBORN

The neonatal cardiovascular system differs from those of fetal, pediatric and adult patients. At term a neonate must successfully transition through abrupt changes in the cardiorespiratory system including changes in the lung volume and compliance and changes in the left and right heart preload and afterload. Intracardiac and extracardiac shunts via the foramen ovale and ductus arteriosus have varying effects on immediate postnatal hemodynamics. The neonatal heart may also have

to cope with structural heart disease and extracardiac congenital and acquired conditions such as congenital diaphragmatic hernia, sepsis, or pulmonary hypotension. A premature birth has to cope with the immaturity of the cardiovascular system and other organ systems, which makes it even more difficult for the neonate to appropriately respond to the challenges of postnatal transition and extrauterine existence.

TRANSITION FROM FETUS TO NEONATE

An understanding of perinatal cardiovascular physiology is essential if subsequent interventions are to be logical rather than merely treating figures. One also needs to understand the characteristics of the fetus and the premature infant which is different from a child or an adult. In the fetus myocytes are smaller and typically have a single nucleus compared with the multinucleated myocytes that are prevalent in later life. Although the fetus has a higher indexed myocardial mass, the fetal myocardium is less organized at the cellular level with fewer sarcomeres per unit mass, different isoforms of contractile proteins, a developing sarcoplasmic reticulum, an overall higher water content and a decreased number of mitochondria. In addition, the heart is enclosed within a poorly compliant thorax. As a result of these factors, the fetal heart is less compliant and less contractile than a term newborn or adult heart. These differences are manifested in the developmentally regulated limited fetal cardiac response to changes in preload or afterload, with changes in the heart rate to alter fetal cardiac output although some response to preload occurs if afterload remains constant. The fetal right and left ventricles also differ in myofibril architecture throughout gestation, with the right ventricle less tolerant to increases in afterload despite its contributing slightly more to the combined ventricular output than

the left ventricle during fetal life. The fetal pulmonary vasculature also exhibits significant differences from the adult pulmonary circulation. In the fetus, the pulmonary arteries are larger, preacinar vessels demonstrate significant elastin in their medial layer with a relative paucity of pulmonary smooth muscle in contrast to the more distal preacinar and acinar vessels which have a predominance of pulmonary smooth muscle in the media and the most distal inter acinar vessels with no smooth muscle medial layer. These differences all result in the fetal pulmonary vasculature limiting fetal pulmonary blood flow to 11 to 22 percent of the combined cardiac output from early-to-late gestation, respectively.

After birth, there is a decrease in pulmonary vascular resistance secondary to ventilation and lung expansion, increasing the arterial pO_2 . The exact mechanism of oxygen induced pulmonary vasodilation during the transition remains unclear. The increase in pulmonary arterial oxygen tension occurs with decreased pulmonary vascular resistance, either directly by dilating the small pulmonary arteries or indirectly by stimulating the production of vasodilator substances, such as phosphoglucose isomerase (PGI), bradykinin, or more importantly nitric oxide.

After birth, the preload to the right heart increases because of cessation of umbilical venous return and also a decrease in pulmonary vascular resistance increases the blood flow to the left side of the heart which allows the flap of the foramen ovale to close functionally soon after birth in term babies, but it can take longer to close in very premature babies. Additionally, the ductus venosus is functionally closed immediately with cessation of the umbilical venous flow. The functional closure of ductus arteriosus however happens slowly over the first several hours or days in term babies under the effect of circulating prostaglandin E_2 and other vasoactive factors and its fully developed muscular medial layer closes it structurally in a few days time. In premature babies, however, it lacks the muscle in the medial layer and allows the ductus to be patent causing the changes in the circulation affecting cardiorespiratory adaptation. Myocardial contractility is also affected by increased levels of thyroid hormone, corticosteroids and catecholamine surge that occurs with labor and delivery.

HEMODYNAMIC ASSESSMENT ON THE NEONATAL UNIT

Traditionally hemodynamic assessment of the sick and premature newborns on the neonatal intensive care unit utilize the clinical assessment tools, such as blood pressure monitoring, capillary filling time, core temperature peripheral difference and the investigations such as blood lactate and base deficit to assess perfusion. These are however limited by low sensitivity and specificity and have poor correlation with cardiac output. Newer modalities such as echocardiography, near infrared spectroscopy

and other noninvasive methods of assessing hemodynamics allow quantification of flows and oxygen extraction. When such advanced modalities are used alongside clinical assessment, they could allow better understanding of the cardiopulmonary interaction and could aid clinician in targeting therapy to the underlying problem.

Clinical Assessment

Assessing clinical signs is part of any medical or nursing training. Heart rate, skin temperature and blood pressure are standard nursing observations. However in the critical ventilated neonate it is desirable to identify cardiovascular dysfunction before it becomes irreversible. Capillary refill time is a poor predictor of cardiovascular function in adults, children and neonates and cannot be recommended as a dependable sign. An increase in heart rate was once thought to be the major mechanism for increasing cardiac output but this is now known to be incorrect in human neonates. Increasing heart rate will still often increase cardiac output but tachycardia has a low specificity for predicting cardiovascular compromise. Similarly evidence of reduced urine output and a baby's decrease in spontaneous activity may be important elements of overall evaluation but are not individually predictive. Moreover base deficit on blood gas are nonspecific indicators of problems in which cardiovascular dysfunction may be primarily or secondarily involved. Lactate can predict poor outcome but as yet is not useful in directing any intervention although future research incorporating other parameters with serial lactate measurements may be more helpful.

Blood Pressure

Blood pressure is regularly monitored in preterm and term babies receiving intensive or high dependency care. Initial normative ranges were reported for small selected groups of babies in the first 12 hours of life with no long-term outcome data. There have been variations in the way blood pressure values are monitored and interpreted. The common ways of monitoring blood pressure include intra-arterial blood pressure using umbilical arterial catheter or peripheral arterial line, oscillometric methods utilizing the Dynamap and the Doppler measurements of blood pressure. It has been shown that the correlation between the Dynamap blood pressures and intra-arterial blood pressure is poor, however the Doppler measurements of systolic blood pressure are comparable to intra-arterial monitored blood pressures.

There have been various practices utilizing different blood pressure references for taking clinical action such as use of gestation equivalent mean blood pressures, mean blood pressures below 30 mm of mercury in premature babies and systolic blood pressure values. Initial normative ranges for mean blood pressure were reported for a

Fig. 1: Systolic blood pressure nomogram (Tin W. Northern Neonatal Nursing Initiative. 1999)

small selected group of babies in the first 12 hours of life with no long-term outcome data. The Northern Neonatal Nursing Initiative in the North of England published population-based normative data for systolic blood pressure for the first 12 days of life.¹ This data was obtained from 398 babies of less than 32 weeks gestation at birth who were free from severe disability at two years of age and is the best normative population data available with known outcomes (Fig. 1).

Subsequent work has demonstrated that blood pressure values can be affected by the presence of the fetal shunt such as patent ductus arteriosus. In the presence of PDA the mean blood pressure values have been found to have no correlation with the cardiac output. However, systolic blood pressures were reported to have moderate correlation with the left ventricular cardiac output.² The timing of the measurement of blood pressure is also important and the values in the first four to six hours of life while the physiological adaptation is taking place results in wide variations and such values are difficult to interpret.

ECHOCARDIOGRAPHY FOR HEMODYNAMIC ASSESSMENT

Functional echocardiography or point of care echocardiography has rapidly evolved in the last decade. Clinicians now recognize its value in the assessment of the sick or premature infants requiring intensive care for assessment and guiding management.³ The reasons for this are essentially pragmatic. Ultrasound evolved as a clinical tool during the 1970s and early 1980s. The provision of real time

information on cardiovascular performance and systemic hemodynamics, noninvasive nature of the technique, rapidity of data acquisition and report generation emulated to perform longitudinal functional assessments have all contributed to the increased use of functional echocardiography by the neonatologists in the neonatal intensive care unit.⁴

Imaging the Newborn

Echocardiographic evaluation of the newborn is complicated by the issues related to patient size and the acoustic window. Ideally care should be taken to maintain the temperature, prevent infection and to minimize duration of contact with the patient. As far as possible the serial scan should be performed by the same examiner as this would reduced the interobserver variability. There are however now efforts to standardize the echocardiographic assessment for hemodynamics and recommendations suggested for a common approach (Fig. 2).

To interpret and assess the cardiac function high quality imaging is essential particularly when Doppler interrogation of vessels is being performed to evaluate blood flow. In preterm babies image quality may be compromised in the presence of hyperinflated lungs. Imaging neonates with bronchopulmonary dysplasia often poses a particular challenge as the hyperinflated lungs shields the areas of interest and may obstruct the views of heart.

Two-dimensional Echocardiography Methods

Two-dimensional imaging is the most common modality to study the structure and anatomy of the heart. Using

Fig. 2: Functional echo basic views

the sector view the frame rate of the probe is the number of sweeps per second. In order to generate seamless images of the moving myocardium the frame rate needs to be faster than the heart rate of the infant. The two important parameters to consider while acquiring images using the frequency of ultrasound waves is image quality and resolution. Higher frequencies provide enhanced image resolution but a lower power admissible for infants limits the depth of the image. Conversely, lower frequencies can reach deeper into the tissue but with poor image resolution. Ideally 7.5 to 10 megahertz of probe frequency rates provide excellent resolution with adequate tissue penetration.

M-mode Echocardiography

The M-mode scanning interrogates moving tissue along a single line with respect to time. In M-mode, the time base is displayed in a sideways fashion but perpendicular to the line of interrogation. The clinical applications of M-mode echocardiography include the estimation of the chamber size, valve thickness, valvular motion and quantification of the myocardial contractility. This requires clear signals, precise measurements and appropriate cuts. Again the standardized measurement techniques have been described which should be utilized while reporting the results.

Doppler Imaging

The Doppler effect of physical principles is a term given to the change in frequency of a wave experienced by an object when there is relative movement between the object and the wave transmitter. In echocardiography, the probe

is the stationary object and the red cells are the moving objects. The difference in frequencies is expressed as an audible pitch and velocity on the screen. The clinical applications of Doppler include continuous wave Doppler, pulse wave Doppler and color flow Doppler methods.

Continuous Wave Doppler

Using continuous wave Doppler, the transducer generates continuous waves with simultaneous wave reception. The main advantage of this modality is the ability to accurately measure blood flow at high velocity. This is particularly important when assessing infants with a restrictive ductus arteriosus, pulmonary hypertension, tricuspid regurgitation and valvular abnormalities and septal valve defects. These lesions usually have valve velocities of more than 2 meters per second and require continuous wave Doppler for ideal examination and assessing the flow pattern and calculation of the velocity. The velocities are also utilized in calculating the pressure gradient. The calculation of peak velocity of the regurgitant jets using continuous wave Doppler such as in tricuspid regurgitation can give the right ventricular pressure estimation. This is calculated using the Bernoulli's equation:

$$\text{Pressure (mm of Hg)} = 4 \times (\text{velocity})^2$$

Continuous wave Doppler is however limited by the lack of selectivity and depth recognition and it would calculate and take into account the velocities of all the flows in its line.

Pulse Wave Doppler

The main advantage of pulse Wave Doppler is its ability to provide a Doppler-shaped data specifically from a small segment along the ultrasound beam, referred as a sample volume or pulse gate. The angle of insonation for a pulse gate is important so that the angle of Doppler beam to the blood flow is less than 15 percent otherwise it would add to the error in calculated value. Pulse gate Doppler has a limitation that it is unable to accurately measure velocities more than 1.5 to 2 meters per second due to a phenomena called aliasing. Aliasing on the screen shows as an abnormal velocity exceeding the rate at which the Pulse gate system can record it properly and gives the illusion that the examined flow is traveling backwards.

Color Flow Doppler

Color flow Doppler is used routinely and commonly utilized to assess the direction of flow of blood. Traditionally, the blood flow occurring towards the probe is taken as red and away from the flow is taken as blue. It is very useful in identifying the areas of flow acceleration or flow regurgitation across valves, septal defects of transseptal shunts.

Fig. 3: Calculation of fractional shortening

Echocardiography for Hemodynamic Assessment in Clinical Practice

Ventricular Function

It is important to remember that ventricular function (or myocardial fiber shortening) and ventricular output are not the same although they are clearly related. Ventricular function and cardiac output need to be measured and considered separately while also assessing preload and after load to gain a more complete hemodynamic picture.

Fractional Shortening

Fractional Shortening (FS) is the most reproducible and commonly used assessment of left ventricular contractility. It is assessed in the long axis parasternal view using a M-mode echocardiography (Fig. 3). It is calculated using Left ventricular end diastolic diameter (LVEDD) and Left ventricular end systolic diameter (LVESD) as:

$$FS (\%) = \frac{LVEDD - LVESD}{LVEDD} \times 100$$

The normal range of fractional shortening for pre-term neonates is 25 to 40 percent. However, this measurement is affected by both preload and afterload. The errors may also occur because of the distortion of the left ventricle in the pre-term infant and the paradoxical septal valve motion associated with right ventricular dominance. The other parameter used is the mean velocity of fiber shortening (velocity of circumferential fiber) which is an alternative measurement of contractility and is less sensitive to minor damage and discrepancies and involves no assumption about ventricular shape. However, it is also influenced by volume loading of the left ventricle which tends to increase both measurements.

Tissue Doppler Imaging

Tissue Doppler imaging (TDI) is a relatively new ultrasound technology that derives measurements of contraction and relaxation velocities directly from the myocardium. As it is a direct measurement it is affected less by preload and afterload and normal values have been documented. However, as yet it can only be seen in an area for further

promising research as there is wide intraobserver and interobserver variability.

Measurement of Cardiac Output

Doppler assessment of left and right ventricular output provides the hemodynamic information regarding the adequacy of blood flow. Assessment of LVO involves measuring the mean velocity of blood flow across the ascending aorta from an apical five chamber view using pulse gate Doppler and determining the diameter of the aortic root from the parasternal long axis view. The maximum ascending and descending aortic velocity in pre-term infant is usually less than 2 meters per second in the absence of valvular disease and hence pulse gate Doppler is better suited for this analysis.

The left ventricular output (LVO) is calculated using the formula:

$$LVO (\text{ml/min}) = \text{Stroke volume} \times \text{heart rate}$$

$$\text{Stroke volume (ml/cycle)} = \text{VTI} \times \text{Cross-sectional area of vessel} (\pi r^2)$$

The VTI (velocity time integral) is calculated from the Doppler trace at the aortic outlet in apical 5 chamber view. It is the area under one cardiac cycle and denotes the measure of a distance traveled by blood during a given beat. The stroke volume depicts the volume of blood ejected in one cardiac cycle. If we multiply the stroke volume by the heart rate it gives the total left ventricular output. When the left ventricular output is divided by the weight of the child it gives the cardiac index which allows it to compare across the patients and is used as a reference data. The normal values for the left ventricular output range from 170 to 320 ml per kg per minute.

One needs to be careful while interrogating the values of the left ventricular output particularly in the presence of the left to right shunt such as patent ductus arteriosus commonly seen in preterm infants. In the presence of a PDA, the left ventricular output overestimates the LV cardiac output and in these situations it has been suggested that right ventricular outflow measurement (Right ventricular output, RVO) would have better correlation with the systemic flow as it is less compounded by the presence of a PDA.⁵ However, RVO measurements can also be affected by the presence of shunts such as patent foramen ovale.

The measurement of right ventricular output can also be done utilizing the same approach as described above. The pulmonary artery diameter is assessed from the oblique parasternal long axis view and the right ventricular velocity time integral is obtained from the Doppler interrogation in the same view in line with the flow in the pulmonary artery. The pulmonary artery diameter calculated in this view of parasternal short axis view is used to compute the cross-sectional area of the vessel.

Superior Vena Cava Flow

As already mentioned the right ventricular output is less affected by the presence of a PDA however the turbulence in the pulmonary artery from the ductal flow can disturb the flow pattern making accurate determination of the RVO difficult. In these situations, superior vena cava flow has been proposed to be a better echocardiographic measure of systemic blood flow as it reflects exclusive venous return from brain and upper body and is unaffected by the shunt. For measurement of the superior vena cava flow a subcostal approach is utilized to gain the SVC Doppler signals and using the pulse gate Doppler interrogate the flow pattern utilizing the technique described above. The SVC diameter is calculated using the modified high suprasternal view and the diameter of the SVC is calculated at a point where it starts funneling. Recently with the availability of the MRI data SVC flow measurements have been challenged due to the crescent shape of SVC in cross-section pressed by pulsating aorta.⁶ It is said to have wide variations in the calculated values and dependent on point of measurement of vessel diameter and calculating VTI in SVC in a baby spontaneously breathing at high rates. The SVC flows of less than 40 ml per kg per minute in the first 24 hours of life have been shown to be associated with the late interventricular hemorrhage which tended to occur as perfusion improved⁷. For objective intervention of hypotension, SVC flows are utilized in proposed trials to selectively identify the babies to target treatment using the normative values.

Diastolic Performance of Myocardium

The diastolic performance is altered in the newborn but its relevance to clinical decision-making is not well appreciated. The diastolic filling is influenced by the compliance of the ventricular wall. As the transmitral flow occurs in two phases, i.e. an early phase of passive flow during which the majority of the filling occurs, and a late period of the late atrial contraction phase during which the remaining third of the venous return to the ventricle is delivered. In patients with diastolic dysfunction the majority of filling occurs during the atrial phase as the stiff ventricular wall prevents passive early flow across the mitral valve. The immature fetal and preterm myocardium is characterized by the impaired diastolic function. Utilizing the pulse wave Doppler and the tissue Doppler imaging, the first phase of early wave (E wave) reflects the passive blood flow across the atrial ventricular valve in early diastole. The second phase is the atrial contraction wave (A wave) and is the result of atrial contraction at the end of diastole. The maximum E and A wave velocities are compared as ratios. The E/A ratio of less than one indicates diastolic dysfunction (indicating a noncompliant ventricle).

The TEI Index (or myocardial performance index) has been found to be a valuable quantitative echocardiography

index of ventricular function by incorporating both systolic and diastolic performance of the right and left ventricles.⁸ It is defined as the sum of iso-volumetric contraction and relaxation times divided by the ejection time, which requires measurement of the time interval between the end and onset of the mitral or tricuspid inflow (the A interval) and the ejection time of the left ventricular or right ventricular outflow (the B interval).

$$\text{TEI Index} = A - B/B.$$

The TEI index is easy to calculate, reproducible and independent of heart rate and blood pressure. Normal values in the healthy neonates range from 0.25 to 0.38. It is also relatively independent of age and has a low degree of inter- and intraobserver variability.

Pulmonary Pressure Measurements

Pulmonary pressure measurements are usually required to assess pulmonary hypertension at birth, persistent ventilatory support with suspected cor pulmonale or after cardiac surgery. This particularly poses a significant problem in the immediate postnatal period as differentiation from an underlying structural heart disease is important.

Once structural heart disease is ruled out there are various functional echocardiography techniques to ascertain right sided pressures. Serial echo can also be utilized to assess response to nitric oxide therapy or for progression of PPHN. The evaluation of pulmonary hypertension may be divided into 1. Evaluation of severity of pulmonary hypertension, 2. Evaluation of the impact on RV performance and pulmonary hemodynamics, and 3. Evaluation of the impact on LV performance and systemic blood flow.

Evaluation of Severity of Pulmonary Hypertension

The RV systolic pressures (RVSP) are calculated using indirect method and utilizing Bernoulli's equation.

$$\text{RVSP} = 4 V^2 + \text{Right atrial pressure}$$

The maximum velocity of tricuspid regurgitation jet is calculated in apical 4 chamber view using CW Doppler. This method has a limitation of inability to calculate the RV systolic pressures in the presence of RV dysfunction.

Patent ductus arteriosus with unrestricted flow can also be utilized to estimate the pulmonary pressures. The peak velocity of right to left transductal flow can be utilized using Bernoulli's equation to calculate pressure difference between systemic and pulmonary circulations. Additionally direction of ductal shunt can be used to evaluate the severity of pulmonary hypertension.

In absence of these shunts such as chronic lung disease direct assessment of pulmonary pressures is difficult to calculate. By utilizing PW Doppler in the main pulmonary artery, right ventricular pre-ejection period (RPEP), time to peak velocity (TPV) and right ventricular ejection time (RVET) can be calculated. The normative data of the

Fig. 4: Right ventricular systolic time intervals

indices RPEP/RVET and TPV/RVET are available. If pulmonary pressures rise, RPEP/RVET rises and TPV/RVET falls (Fig. 4).

Evaluation of right ventricular performance and pulmonary hemodynamics

Moderate-to-severe RV systolic dysfunction is obvious by visual inspection. Low RV output (<150 ml/kg/min) may also support a diagnosis of impaired RV performance. Fractional shortening of RV is difficult to measure and interpret as RV is wrapped around LV. In PPHN, RV appears larger and stiffer than the LV, with a dilated out-flow tract and contractility may appear subjectively diminished. The interventricular septum may become flattened due to the rising RV pressure and septal wall motion may be reversed in severe cases.

Assessment of a Patent Ductus Arteriosus (PDA)

Functional assessment of a PDA incorporates; Is the duct patent (Figs 5A and B)? What is its diameter? What is the direction of shunting? Is PDA likely to be hemodynamically important? To evaluate this functional echo is targeted at studying ductal characteristics, evaluate pulmonary hyperperfusion and evaluation of systemic hypoperfusion.

Ductal Characteristics

This includes size of the PDA and ductal flow pattern (Fig. 6). The size of the PDA is calculated at the narrowest point near the pulmonary end with appropriate gain settings. A PDA dimension of >1.5 mm is traditionally taken as significant.⁹ This however varies when treatment is considered for closure in first 72 hours or later when it is symptomatic. The ductal flow pattern is classified into pure right to left as in PPHN, growing pattern with bidirectional flow, pulsatile pattern with high systolic and low diastolic peak velocity and closing pattern with minimal variation in peak velocity between systole and diastole.

Figs 5A and B: Ductal view with PW Doppler

Evaluation of Pulmonary Hyperperfusion

This is assessed using left heart size and LV function. The left heart size is calculated using left atrial to aortic root ratio (LA:AO ratio).¹⁰ A value of 1.5 mm or more is considered to be significant. However in presence of a patent foramen ovale left atrium may be decompressed allowing LA:AO ratio to stay normal even in presence of a large PDA. Left ventricular end diastolic diameter to aortic root ratio of >2.1 is also considered symptomatic. The LV output in presence of a PDA of more than 300 ml/kg/min reflects hyperdynamic circulation. Similarly left pulmonary artery peak velocity of >4.2 m/s is also considered significant.

Evaluation of Systemic Hypoperfusion

This is evaluated using preductal aortic flow pattern, mesenteric or descending aorta diastolic steal and SVC flow. Absent or reversal of diastolic flow in celiac, mesenteric artery or descending aorta reflects ductal steal.¹¹ A low SVC flow (<40 ml/kg/min) in first 24-48 hours and IVO/SVC flow ratio of >4 is also sign of systemic hypoperfusion.

There are various combinations of echo criteria suggested to predict the severity of PDA while defining its significance and grading into small, moderate or large size PDA.¹²

Training and Accreditation

There is a growing acceptance that neonatologist-performed functional echocardiography is a useful tool in the NICU, with increasing evidence of improved patient

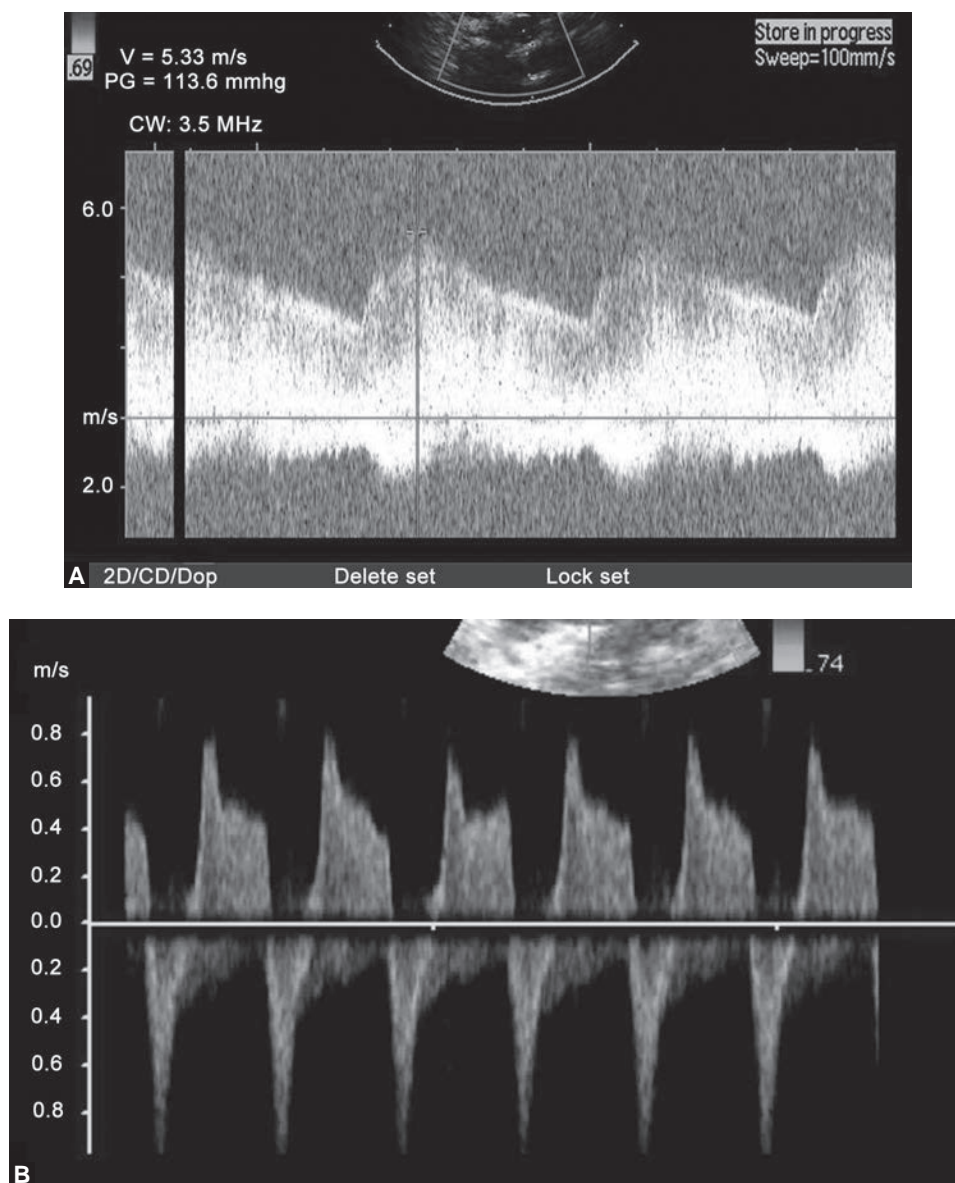

Fig. 6: Patent ductus arteriosus flow patterns

outcomes.¹³ What is lacking at present is a formalized training and accreditation program necessary for the development of echocardiography skills. The potential risks of introducing this skill set without formal training include a divergence from clinical assessments and misdiagnosis of congenital heart disease (CHD).¹⁴ This may result in inadvertent withholding of treatments or instituting incorrect therapies. Collaboration with the pediatric cardiology service is essential in developing standards for practice. It is essential that standards are set to ensure that competence is achieved and maintained with ongoing quality assurance. There are now first guidelines and recommendations published for targeted neonatal echocardiography in NICU.¹⁵

Near Infrared Spectroscopy (NIRS) for Hemodynamic Assessment

NIRS has drawn attention because it provides continuous bedside reading, is easy to apply and is noninvasive. It can monitor the brain and other organs simultaneously, is validated, accurate and precise and has good inter and intra-patient repeatability. It can be used to measure cerebral blood flow, cerebral blood volume and cerebral venous saturation. Various indices can be extracted from NIRS application such as cerebral fractional oxygen extraction (CFOE), cerebral oxygen delivery (CDO_2) and cerebral metabolic rate for oxygen (CMRO_2).

The new generation NIRS monitors have overcome some of the problems of older models such as having more

than one receiving optode, allowing subtraction of contribution from scalp/skull, calculations of estimated distance traveled by scattered light and allowing quantification of measurements of Hb and HbO.

The uses of NIRS include early detection of cerebral autoregulation even in babies who are apparently clinically well but are associated with a higher mortality. Its use is still limited to some neonatal units and outside those units is considered as a research tool as interobserver variability is high and is dependant on the position of application of optode. The concept and advances in this field are promising as it provides direct measure of perfusion of target organ with a potential of allowing early intervention and management.

Other Hemodynamic Assessment Modalities

There are other techniques being tested at point of care such as noninvasive continuous cardiac output monitoring using CW Doppler (US COM) and machines using impedance methods. Volumetric echo using 4D image acquisition and reconstruction looks promising but are limited by the nonavailability of neonatal probes. Same applies for transesophageal echo limited by the size of the probes. Functional MRI is also being researched which allows precise understanding but is limited by the fact that these can be one off examinations rather than point of care serial assessments. Until further validated techniques are available bedside, functional echocardiography remains the gold standard for bedside assessment of hemodynamics. Further efforts are however required to achieve common standards of measurement and special emphasis on training and accreditation is required utilizing telemedicine linked with pediatric cardiology centers.

CHAPTER 8

Apnea

Raktima Chakraborty, Sanjay Wazir

Apnea or cessation of breathing is common in preterm babies born before 34 weeks gestation and almost universal in babies born before 26 weeks. Despite being such a common problem, we are *neither sure of the impact apnea has on the neurodevelopmental outcome of neonates nor are we sure that treatment of apnea by different modalities improves neurodevelopment.*

DEFINITION

Apnea of prematurity (AOP) is found in >50 percent of premature infants and is almost universal in infants who are <1000 g at birth. Most of the available literature defines apnea in infants as breathing pauses which last more than 20 seconds, or a shorter duration if associated with bradycardia or oxygen desaturation.¹ However, there is no consensus about the duration of apnea, the degree of change in oxygen desaturation, or severity of bradycardia that should be considered pathologic, i.e. we don't have an answer as of now whether an apnea which last 20 seconds will have the same connotation as a pause for 40 seconds and whether apnea which leads to desaturation to a value of 30 percent will differ in neurodevelopmental outcome from an apnea which results in a oxygen saturation levels of 80 percent. Apnea events exceeding 30 seconds are occasionally seen in both healthy term and preterm infants.² This suggests that apnea duration *per se* may not be the critical feature of altered breathing and its relation to circulatory consequences. Lack of standardization of this data is the most important reasons for ambiguity in outcome measure in neonatal apnea.

CLASSIFICATION

- *Central apnea (40%):* Both the inspiratory effort and airflow cease simultaneously in this type of apnea (Absence of chest wall movement and airflow).

- *Obstructive apnea (10%):* This type is characterized by absence of airflow in the presence of inspiratory efforts (Presence of chest wall movement but no airflow).
- *Mixed apnea (50%):* Central apnea is either preceded or followed by airway obstruction. Central apneas tend to be shorter, whereas the obstructions tend to prolong the episodes and accelerate the onset of bradycardia.

PATHOPHYSIOLOGY

Although pathogenesis of apnea of prematurity has not been fully elucidated, it is probably related to both the overall neurological and cardiorespiratory immaturity of preterm babies. Apnea of prematurity results from immaturity of brainstem respiratory control centers. As immaturity is more pronounced with decreasing gestational age and hence there is more chance of apnea at lesser gestational age. In normal individuals, the respiratory center (situated in the medullary region of brainstem) responds to the various signals like increase in carbon dioxide, decrease in oxygen and decrease in pH by increasing the firing of respiratory neurons. This increased firing results in increased impulses to respiratory muscles and hence results in increased ventilation. These responses are impaired in newborns and this result in apneas.³

Respiratory responses to increased carbon dioxide are decreased in preterm babies and slope of response continues to increase from 26 weeks onwards till 33 weeks and hence in face of hypoventilation due to any reason, babies are not able to increase their respiratory drive and land in apnea.

Responses to hypoxia are also altered in preterm babies. In contrast to events in older infants where hypoxia results in sustained hyperventilation, preterm babies are characterized by a very brief period of hyperventilation followed by depressed ventilation despite continued

hypoxia. Initial hyperventilation may be completely blunted in preterm babies.

Negative pressure in the upper airways in preterm babies can result in inhibition of diaphragmatic contraction. In cases of mixed apneas, the lack of airflow due to obstruction, e.g. due to passive neck flexion, results in generation of a negative pressure in airways and as a result cause decrease in central respiratory drive. One of the mechanism by which CPAP helps in apnea is by splinting the upper airways and hence obviating this reflex inhibition. Also neonates are obligate nose breather and cannot make an immediate switch to oral breathing when nose is obstructed.

Active or REM sleep is marked by irregularity of tidal volume and REM sleep predominates in preterm infants. Coupled to this fact is that chest wall compliance of premature infants is poor and hence they have more episodes of hypoventilation.

APNEA AND NEURODEVELOPMENT

Since apnea is associated with desaturation and bradycardia, it is plausible to think that significant episodes of apneas may have a significant impact on neurodevelopment. However, this information at present is not clear. Earlier reports found little evidence of any neurodevelopmental risk directly attributed to a history of apnea of prematurity or ALTE.^{4,5} Studies are few due to non-standardized criteria for diagnosis and for quantifying severity of apnea related events in NICU and also due to variable treatment strategies. Also separating the consequences of conditions associated with premature births like sepsis, intraventricular hemorrhage from effects of apnea of prematurity has proven difficult.

Cheung et al⁶ followed 124 very low-birth-weight babies to 24 months of age to evaluate the relationship between precisely measured pre-discharge apnea that persisted beyond 35 weeks and the neurodevelopmental outcome. They found that duration of artificial ventilation and the grade of IVH were independent predictors of neurodevelopmental outcome and the mean oximetry desaturation and frequency of pre-discharge apnea correlated with mental and motor developmental scores. Mean oximetry desaturation during apnea was an independent predictor for both mental and motor scores in infants with grade 3 or 4 intraventricular hemorrhage. Authors suggested that pre-discharge respiratory recordings may be useful in predicting subsequent neurodevelopment of high-risk preterm infants, especially those with severe intraventricular hemorrhage. Increasing number of days on which at least one apnea occurred also has been associated with impaired neurodevelopmental outcome.⁷ In the same study number of days, ventilation was required for apnea was also associated with poor neurodevelopmental outcome. Even delay in resolution of apnea beyond the

36 weeks postconceptional age has been associated with impaired neurodevelopmental outcome.⁸ Apnea of prematurity has been shown to be an independent predictor of poor early school age outcome like cognitive functions and other neuropsychological rating.⁹ These events are probably related to hypoxemia/blood flow during the episodes of apnea. CHIME study¹⁰ also provides some insights regarding risk of neurodevelopmental sequel in infants with events documented using home memory monitoring. Of the infants included in the study, there was an inverse relation between number of conventional events detected by home monitoring and neurodevelopmental outcome. This association was seen both in term and preterm babies. The adjusted difference in mean MDI scores with at least five events compared to no events was 5.6 points lower in full term babies and 4.9 points lower in preterm babies. A dose effect was also suggested by tendency for mean BSID-II values with 1 to 4 events to be intermediate between 0 and at least 5 events. Changes in cerebral blood flow velocity have been documented to decrease to the level of no or minimal diastolic blood flow during prolonged apnea.¹¹

Although no authoritative statements can be made based on sparse data, it may be worthwhile keeping a close check on neurodevelopment in newborn *with recurrent apneas and in whom the apneas persist beyond term gestation*. Validity of pre-discharge apnea event recording still has to be confirmed in larger trials before it can be used as a predictive tool for neurodevelopment in newborns.

MONITORING AND EVALUATION OF APNEA

Who all to Monitor

All infants less than 35 weeks of gestation should be monitored for apneic spells for at least the first week of life because of high risk of apneas in this group of babies. Apneic spells generally begin after 24 hours although it can begin on the first postnatal day of life also. Progesterone (which is a known respiratory stimulant) transferred from the mother before delivery has been suggested as the reason for the delayed presentation of apnea. In addition *term babies who have any central nervous system disorder, systemic illness or has received drugs which depress respiration like narcotics, etc. should be monitored for apnea*.

Routine monitoring for apnea includes monitoring of heart and respiratory rates as well as oxygen saturations since impedance monitors cannot detect obstructive apneas. Polysomnogram which measures cardiorespiratory patterns, muscular activity, ET_{CO}₂, Tc_{CO}₂, oral and nasal flow and chest and abdominal movements is ideal but is not routinely used in clinical practice.

How Long to Monitor

Both term and preterm babies show a progressive decline in apneic episodes over time. In a old citation involving

249 term and preterm infants, 92 percent had no further apnea beyond 37 weeks and by 40 weeks 98 percent of the babies were apnea free.¹² That study involved larger preterm babies. In a recent study involving preterm babies between 24 to 28 weeks, apnea frequently persisted beyond 36 weeks and continued beyond 40 weeks post-conceptual age in some.¹³ CHIME study data showed that cardiorespiratory events in preterm babies return to baseline normal level at 43 to 44 weeks postconceptional age. Only one study till date has attempted to answer the question of what constitutes a safe period and it concluded 8 days as a safe period but again there is paucity of data in extremely premature babies.¹⁴

Hence based on available literature, one should monitor for apnea till at least 37 weeks gestation, but in extremely premature babies one may have to monitor for a longer time. *Apnea free period of 8 days* seems to be a reasonable period to address recurrence.

Role of Home Monitoring

Home monitoring has not shown to decrease the incidence of sudden infant death syndromes (SIDS). Home monitor could be used as an alternative to prolonged hospital stay in babies who are otherwise well but continue to have non-life-threatening apneas at the time of discharge. Such monitoring should continue for a maximum of 44 weeks postconceptional age as suggested by the CHIME study. Infants with frequent events at home should be rehospitalized and have further studies. Additional diagnoses have been diagnosed after admission in such babies.¹⁵

MANAGEMENT OF APNEA

Once apnea is diagnosed, the clinician must investigate for a number of causes while continuing to monitor and provide supportive care (Table 1). In term babies, most cases are likely to have secondary causes of apnea, where as in extremely premature babies, although investigations for secondary causes must be completed, 80 percent of the infants would have no identifiable cause and diagnosis is of apnea of prematurity.

Physical examination should include observation of the infants breathing pattern and careful neurological and respiratory examination. One should look for presence of secretions in the oropharynx which may have resulted in occlusion of the airway. It is particularly important to *rule out systemic conditions like seizures, gastroesophageal reflux as pharmacotherapy with methylxanthines is known to decrease the threshold for seizures and reflux.* Among the first tests to be done is blood sugar, as symptomatic hypoglycemia is independently associated with neurodevelopmental poor outcome. Infants should be evaluated for stability of thermal environment. Other blood tests include complete blood counts for sepsis, electrolytes including calcium. Other test

Table 1: Secondary causes of apnea in a newborn

Central nervous system

Intraventricular hemorrhage, drugs, seizures, hypoxic injury, herniation, neuromuscular disorders, Leigh syndrome, brainstem infarction or anomalies (e.g. olivopontocerebellar atrophy) and effect of general anesthesia

Respiratory

Pneumonia, obstructive airway lesions, upper airway collapse, atelectasis, extreme prematurity (<1,000 g), laryngeal reflex, phrenic nerve paralysis, severe hyaline membrane disease, pneumothorax, hypoxia, malformations of the chest

Infectious

Sepsis, necrotizing enterocolitis, meningitis (bacterial, fungal, viral), respiratory syncytial virus

Gastrointestinal

Necrotizing enterocolitis, GERD (questionable)

Metabolic

↓ Glucose, ↓ calcium, ↓/↑ sodium, ↑ ammonia, ↓ organic acids, ↑ ambient temperature, hypothermia

Cardiovascular

Hypotension, hypertension, heart failure, PDA, anemia, hypovolemia, vagal tone

Other

Immaturity of respiratory center, sleep state, maternal drug

like ECG, chest radiograph, spinal fluid analysis should be carried out based on circumstances.

Best Practice Guidelines for the Prevention and Treatment of Apnea

Prevention of Prematurity

Since the incidence of apneas is directly related to the gestational age at birth, decrease in incidence of premature births may offer the simplest solution to decrease the incidence of apneas. However, this is most difficult to achieve.

Tocolysis

Tocolysis has not been able to prolong a preterm birth for long-time in preterm labor. In fact, magnesium sulphate used for pre-eclampsia and tocolysis in mother has been associated with increased risk of apneas in neonates.¹⁶ Hypermagnesemia during parenteral nutrition has also been a cause of apnea.¹⁷

Antenatal Steroids

Although antenatal steroids do not directly affect the maturation of respiratory centers, it does decrease the incidence of respiratory distress syndrome which can present as apnea in extremely premature babies.

Noxious Stimuli

Like deep suctioning, painful procedure should be avoided or done gently as these promote a vagal inhibition of respiration.

Kangaroo Mother Care

Skin-to-skin contact or kangaroo care for preterm infants has been associated with an increased occurrence of apnea, bradycardia and desaturation and irregular breathing;¹⁸ this appears to be unrelated to hyperthermia.¹⁹ The observation suggests that obstructive events may occur during skin-to-skin contact. Recent investigators however found no adverse events during kangaroo care.²⁰ The disparity among the reported studies may be related to the specific practice of skin-to-skin care in a particular NICU or the validity of monitoring during skin-to-skin contact. Till further data is available, given the benefits of KMC in reducing serious infections and preventing hypothermia in preterm babies (which independently increase the risk of apneas), KMC does hold promise in care of premature babies.

Blood Transfusions

Classical teaching recommends red blood cell transfusions, if apnea coexisted with anemia. However, data available at present in preterm babies with both mild (Hb 8-12 mg/dl)²¹ and moderate anemia (<8 mg/dl)²² have shown that giving transfusion to such babies does not decrease the episodes of hypoxia/bradycardia. Given all the hazards associated with blood transfusions in neonates, apnea of prematurity alone should not be an indication for transfusions.

Sensory Stimulation

Introduction of pleasant odor in the incubator in preterm babies who continued to have apneas despite pharmacological therapy has been shown to decrease the incidence of apneas by almost 30 percent.²³ Presence of a pleasant odor in the environment may help the infant to regulate his physiological state, however it is possible that vanillin used in the study possesses pharmacological properties and therefore has direct or indirect effects on the respiratory centers. Since, some of the odors can have negative influence on the respiration use of this modality *should wait further trials*.

CO₂ Inhalation

Although one of the pathophysiological mechanisms of apnea is decreased respiratory drive to increased CO₂ in the blood, inhalation of low concentration of CO₂ has also been proposed as an effective treatment. In one study involving 10 preterm babies with gestational age between 31 to 33 weeks exposure to 1 hour of CO₂ concentration

ranging from 0.5 to 1.5 percent was associated with significant decrease in the episodes of apnea and improved oxygenation. This data *however is too limited to recommend this therapy at this time*.²⁴

Oxygen Supplementation

Oxygen may decrease the frequency of apneas by replacing functional residual capacity gases by oxygen and ensuring that during brief episodes of apnea there is enough oxygen in the lungs to diffuse into the blood and avert hypoxemia. However, oxygen therapy in the neonates is fraught with dangers of oxygen mediated free radical injury like BPD, ROP, etc. *Hence, oxygen should be used to keep the pulse oximeter values in the 88 to 93 percent range*. If a newborn requires oxygen supplementation to keep oxygen saturation in that range, then one must search for secondary causes of apnea like sepsis, PDA, etc. and not label as apnea of prematurity.

Temperature

Hypothermia is a known risk factor for apnea and should be avoided or corrected before considering any further therapy. Increase in ambient temperature to 30°C has been shown to increase the incidence of apneas in preterm babies reaching term as compared to the keeping the babies at 24°C.²⁵ Even a slight increase in body temperature of 0.8°C increased the indices of periodic breathing with apneic oscillations.²⁶ Air temperature in an incubator *should be kept near the lower end of the thermoneutral zone to lessen the episodes of apnea*.

Position

Extremes of flexion and extension should be avoided to decrease the likelihood of airway obstruction. Although physiologically ventilation is better in prone position, central apneas tend to be more in prone position²⁷ with less arousals emphasizing the importance of recommending supine sleeping after neonatal unit discharge for prematurely born infants.

Kinesthetic Stimulation

Physical stimulation by nursing staff is commonly used to arouse the apneic infant and stimulate breathing. This led people to speculate whether frequent physical stimuli by means of oscillating mattress to provide kinesthetic stimulate breathing and might reduce the number of apneic events. Kinesthetic stimulation has not been shown to prevent occurrence of apnea.²⁸ Cochrane review²⁹ on kinesthetic stimulation to treat established apneas has shown decreased frequency of apnea of short duration but had no impact on the clinically significant apneas (those more than 20 secs in duration or those with hypoxia and bradycardia). The studies included in the review all used a different

method of providing stimulation and because of the cross-over design later outcomes on neurodevelopment could not be studied. *Further research with larger trials is needed with focus on neurodevelopment before recommending this modality.*

Carnitine Supplementation

Preterm infants have lower muscle carnitine reserves compared to term infants. This is probably related to poor tissue uptake due to immaturity of the carnitine biosynthetic pathways, reduced placental transfer and reduced intakes from breast milk. Treatment with carnitine has shown benefit in the respiratory status of ventilator dependent adults, as well as stabilization of respiratory parameters and increased physical performance in adult patients with chronic respiratory insufficiency. Cochrane review³⁰ on carnitine for apnea has shown no benefit and *hence its use at present is not recommended.*

Immunization

There is an increase in adverse cardiorespiratory events following the first dose of DTP-IPV-Hib in preterm infants. The increase in apnea has been attributed to the whole-cell pertussis component.³¹ Investigators have observed reduced morbidity with newer vaccines that contain acellular pertussis.³² However, one recent study showed no difference between those who received whole cell as compared to the acellular variant.³³ Chronic diseases in preterm babies at the time of immunization greatly increased the risk of apneas.³⁴ If the neonate is in the NICU for chronic diseases at 2 months post-birth, *monitoring for apnea, bradycardia and desaturation is recommended after vaccination.* Healthy preterm infants without chronic disease and therapy seem to be less vulnerable to such adverse effects *but still should be vaccinated in hospital settings.* Acellular pertussis should be used for immunization in preterm babies if cost is not a factor.

Pharmacological Treatment

There are no definite guidelines as when to start pharmacological therapy but most would start treatment when apneic spells continue despite supportive measures or if one apneic episode was severe enough require bag and mask ventilation.

METHYLYXANTHINES

Most commonly prescribed drug therapy for AOP.

- Caffeine
- Aminophylline and its oral substitute theophylline.

Mechanisms of action of methylxanthines

- Increased response to CO₂ and decreased hypoxic depression of central respiratory drive
- Increased diaphragmatic activity
- Increased minute ventilation.

Pharmacokinetics

Theophylline

Mean half-life of theophylline is approximately 30 hours in infants. Oral theophylline is given with a loading dose of 5 mg/kg followed by a maintenance dose of 1 to 2 mg/kg every 8 hours. A therapeutic effect is seen at a plasma concentration of at least 5 mg/L, although a target plasma concentration is around 10 mg/L. Plasma concentration of theophylline may vary widely at the same dosage levels, which necessitates frequent monitoring and dose adjustments.³⁵ Toxicity usually starts after 20 mg/L but can be seen at plasma concentration of more than 13 mg/L. Side effects include tachycardia, abdominal distention, feeding intolerance, seizures, hyperglycemia and electrolyte imbalances.

Caffeine citrate can be administered either orally or intravenously. The recommended loading dose of 10 mg/kg of caffeine (equivalent to 20 mg/kg of caffeine citrate) followed 24 to 48 hours later by a single daily maintenance dose of 2.5 mg/kg (5 mg/kg of caffeine citrate). Caffeine toxicity is rarely observed at plasma serum concentration below 50 mg/L, which is markedly higher than the serum therapeutic concentration of 5-20 mg/L. Side effects commonly seen with caffeine are jitteriness, tachycardia and occasionally GI intolerance is reported.

Choice of methylxanthine therapy: Evidence suggests that caffeine is equal in efficacy with fewer drawbacks.³⁵ Dosing regimens of caffeine are simpler and produce more predictable results. Moreover, caffeine has a wider therapeutic window and required very infrequent monitoring of plasma levels.

Reasons for Concern with Methylxanthines

Xanthines inhibit two (A1 and A2a) of the four known (A1, A2a, A2b and A3) adenosine receptors and experimental evidence suggests that *nonspecific adenosine receptor blockade in very preterm infants may have detrimental effects on growth, neurological and cognitive development and childhood behavior.*

Effect on Growth

Methylxanthines increase oxygen consumption³⁶ in preterm babies by 20 to 25 percent and it has been shown that even a single loading dose of theophylline 5 mg/kg can increase the energy expenditure by 15 kJ/kg/day. This data although not conclusive suggests that use of methylxanthines may increase energy consumption and hence effect growth of premature babies.

Effect on Neurological Development and Behavior

Adenosine is neuroprotective in many experimental models of hypoxia/ischemia.³⁷ However, the results are not consistent and Bona et al³⁸ found that theophylline reduced rather than increased brain injury after hypoxia-ischemia

in 7-day old rats. Efforts to manipulate adenosine receptors in neonatal and adult animal models of hypoxic-ischemic brain injury with specific agonists and antagonists for the adenosine A1 and A2a receptors have yielded complex and occasionally contradictory results. Furthermore, there is an evidence that chronic administration of adenosine receptor ligands has different effects on hypoxic-ischemic brain injury than acute ligand administration.³⁹ Mice with experimental deficiency of A1 and A2 receptors are more anxious and aggressive.⁴⁰

But the famous CAP trial (Caffeine in apnea of prematurity)⁴¹ which involved around 2006 preterm newborn in multiple study centers has demonstrated the safety of this silver bullet. Infants with a birth weight of 500 to 1250 g were eligible for enrolment if their clinicians considered them to be candidates for methylxanthine therapy during the first 10 days of life. The results of this trial showed that caffeine therapy decreased incidence of bronchopulmonary dysplasia and mean duration of mechanical ventilation by a week. Besides, caffeine did not increase the incidence of ultrasonic evidence of brain injury and necrotizing enterocolitis.

Long-term safety data on caffeine therapy for apnea of prematurity has shown that improves the rate of survival without neurodevelopmental disability at 18 to 21 months in infants with very low birth weight.⁴² Effect of caffeine on neonatal morbidities in the CAP trial.

Patent Ductus Arteriosus

That significant reduction in the number of neonates requiring pharmacologic closure of Patent Ductus Arteriosus (PDA) in the caffeine-treated group (293/1006 or 29.3%) compared to placebo (381/1000 or 38.1% $p < 0.001$).

Bronchopulmonary Dysplasia

Bronchopulmonary dysplasia (BPD) rates were significantly lower in the caffeine treated group (350/1006 or 36.3%) compared to the placebo control (447/1000 or 43.2%, $p < 0.001$).

Retinopathy of Prematurity

Caffeine significantly reduced the risk of severe ROP (stage 4 or 5 or had laser or cryotherapy in at least one eye). Severe ROP occurred in only 5.1 percent (49/965) in caffeine-treated infants and in 7.9 percent (75/955) in the placebo control group.

Necrotizing enterocolitis (NEC) and intraventricular hemorrhage (IVH): No protective effect of caffeine on these morbidities.

Long-term Outcome

Death or survival with disability was significantly lower in the caffeine-treated group (377/937, 40.2%) compared to

the placebo group (431/932, 46.2%, $p = 0.008$). Infants who had cerebral palsy was also lower in the caffeine-treated group (40/909, 4.4%) compared to the placebo group (66/901, 6.5%, $p = 0.009$). Those with cognitive impairment was also lower in the caffeine-treated group (293/867, 33.8%) compared to the placebo treated infants (329/858, 38.3%, $p = 0.04$).

Post-hoc subgroup analyses were performed on the basis of: (1) indication for commencement of study drug: treat apnea, prevent apnea or facilitate extubation; (2) positive pressure ventilation (PPV) at randomization: Endotracheal tube (ETT), noninvasive ventilation or none; and (3) timing of commencement of study drug: Early or late (≤ 3 versus > 3 days). Results of this post-hoc analysis showed that effects of caffeine was more in the group who were ventilated within 24 hours of birth and were given caffeine early.⁴³

Based on the above data, it is reasonable in current era to start caffeine treatment in all infants less than 1250 gm, however if one chooses to be a bit more selective then, at least those babies who have an endotracheal tube inserted for ventilation should be started on caffeine early.

Doxapram

Doxapram is a respiratory stimulant that acts on both peripheral chemoreceptors and the central nervous system. Dose: 3 mg/kg bolus followed by 1.5 mg/kg/hr as infusion. Cochrane review on doxapram (only one study) showed decreased apnea in the first 48 hours after starting the drug but the benefit was not sustained. No major side effects were reported. But number of subjects in the study was too small to make useful conclusions. Doxapram has been shown to decrease the cerebral blood flow in preterm babies⁴⁴ and even mental developmental delay has also been associated with prolonged days of doxapram therapy for apnea.⁴⁵ Other short-term side effects like hypertension, central nervous system stimulation, gastrointestinal disturbances and even heart block has been reported in some of the observational studies. Given that there are no substantial data available on the benefit/side effects, doxapram use *should be restricted* to scenarios where recurrent apneas are continuing despite use of methylxanthines and *facilities for ventilator support are not available*. Doxapram infusion could be used to transfer the baby to a NICU with such facilities.

VENTILATION

Continuous Positive Airway Pressure

CPAP delivered by a nasal interface is an effective treatment of apnea of prematurity.⁴⁶ Mechanisms proposed—patency of upper airways, stabilizing chest wall, maintaining functional residual capacity. Cochrane review⁴⁷ comparing CPAP with methylxanthines suggested higher failure rates with CPAP. The only trial included in the review, used mask CPAP—a modality which is no longer

being used. Masks require a complete seal and improper use might have resulted in a higher failure rates. Recent studies on VLBW babies show that early application of nCPAP and avoidance of mechanical ventilation resulted in no adverse neurodevelopment/growth.⁴⁸ A significantly higher developmental quotient was found in the nCPAP group at 18 months' corrected age. Several trends were also noted in the nCPAP group with a decrease of intraventricular hemorrhage and in "abnormal neurodevelopment" at 6 months corrected age. However, these studies were not in babies having apnea. *Prophylactic CPAP has no role in prevention of apnea.*

Nasal Intermittent Positive Pressure Ventilation

If apneas continue despite CPAP and methylxanthines, intubation and ventilation become necessary. Owing to the risks of invasive ventilation, nasal intermittent positive pressure ventilation is an alternative worth considering. NIPPV reduces asynchronous thoracoabdominal motion as a result of better stabilization of chest wall.⁴⁹ Two trials^{50,51} comparing the NCPAP to NIPPV have shown different results—one showing no difference where as the more recent one⁵¹ has shown NIPPV to be more effective in reducing apneas. Gastrointestinal perforation has been reported by some authors.⁵² Newer machines can synchronise ventilator breaths (SNIPP) with the infant's respiratory cycle. For practical purposes NIPPV may be a used if apneas continue despite NCPAP.

Intubation and Assisted Ventilation

If the infant continues to have clinically significant episodes of apnea despite maximum pharmacological and noninvasive positive airway pressure ventilation, intubation and assisted ventilation become necessary.

High-Flow Nasal Cannulae

Recently, it has been shown that NC can deliver positive distending pressure (PDP) to premature neonates if the flow is increased to 1 to 2 L/min (high-flow nasal cannulae [HFNC]). Only one study has compared nasal cannulae (with air oxygen blender) to nasal CPAP. NC was as effective as NCPAP in the management of apnea of prematurity with no difference in the number of apneas, bradycardias, or desaturation during a 6-hour period.⁵³ This is a small study with period of observation limited to 6 hours. The nasal cannulae being inexpensive and easier to use, *need to be studied in larger trials.*

SUMMARY

The treatment of AOP requires trials of multiple strategies. Both pharmacologic and nonpharmacologic interventions carry some risks. The risks of treatment should be

weighed against the risks and consequences of prolonged apnea before starting treatment. For those infants who do receive treatment, appropriate monitoring and a plan for home therapy should be in place. Periodic check-ups for improvements in apnea and a plan for discontinuation of treatment must also be developed to keep the treatment periods as short as possible.

CHAPTER 9

Birth Asphyxia and Hypoxic-Ischemic Encephalopathy

Vikas Mahajan, Sanjay Wazir

Birth asphyxia refers to an impairment of the normal exchange of respiratory gases during parturition, and the ensuing adverse effects on the fetus. It is an important cause of fresh stillbirth and early neonatal death. The condition of a newborn infant is determined by a complex interaction of maternal, placental, uterine and fetal factors extending through pregnancy to delivery. At the core of the fetomaternal unit is the process of placental exchange where by oxygen from the maternal circulation and carbon dioxide from the fetal circulation passively diffuse across the placental membrane. During normal uterine contractions placental exchange is abolished when the uterine pressure exceeds 10 mm Hg. Studies using infrared spectroscopic techniques during normal labor show that many infants undergo intermittent hypoxia during the process of delivery. Despite this hypoxic stress most infants are born in good condition. The fetus who experience significant asphyxia episode is at risk of developing hypoxic ischemic encephalopathy or other end organ damage.

Certain terms are commonly used during evaluation of a baby at risk for brain injury in the perinatal period.

NEONATAL DEPRESSION

It is a general term used to describe infants who have a prolonged transition from intrauterine-to-extrauterine environment and usually have low APGAR scores.

NEONATAL ENCEPHALOPATHY

It is a clinical term used to describe an abnormal neurobehavioral state that consists of a decreased level of consciousness. It characteristically begins within the first postnatal day and may be associated with seizure like activity, hypoventilation or apnea, depressed primitive reflexes and the appearance of brainstem reflexes. It does

not imply a specific etiology, nor does it imply irreversible neurological injury.

HYPOXIC ISCHEMIA ENCEPHALOPATHY

It is an abnormal neurobehavioral state in which the predominant pathogenetic mechanism is impaired cerebral blood flow.

Definition

The major difficulty in collecting accurate epidemiological data on birth asphyxia is the lack of a common definition of the condition. The 1996 guidelines from the AAP (American Academy of Pediatrics) and ACOG (American College of Obstetricians and Gynecologists)¹ for hypoxic-ischemic encephalopathy (HIE) indicate that all of the following must be present for the designation of perinatal asphyxia severe enough to result in acute neurological injury:

- Profound metabolic or mixed acidemia (pH <7) in an umbilical artery blood sample, if obtained
- Persistence of an Apgar score of 0 to 3 for longer than 5 minutes
- Neonatal neurologic sequelae (e.g. seizures, coma, hypotonia)
- Multiple organ involvement (e.g. kidney, lungs, liver, heart, intestines).

However, the National Neonatology Forum of India has defined asphyxia as “gasping or ineffective breathing or lack of breathing at one minute of life”.

Apgar and Birth Asphyxia

Apgar score was devised by Virginia Apgar, an obstetric anesthesiologist in 1952 to express the early postnatal condition of the newborn. It was designed to be a guide to the resuscitation of the newborn. Over time the universality

of the Apgar score led many investigators to adopt it as a marker for birth asphyxia. Most commonly a one minute Apgar less than or equal to three, or a five minute Apgar less than seven have been taken to indicate birth asphyxia. The problems with using Apgar score as a marker of birth asphyxia are:

1. Apgar score may be low because of causes other than birth asphyxia, e.g. prematurity, maternal sedation, neuromuscular disorder, etc.
2. Apgar score has a poor correlation with the long-term outcome. However, the extended Apgar score recorded 20 minutes after birth has much better specificity for the prediction of both early death and disability.²

Cord Blood Gases and Birth Asphyxia

The normal cord blood gas values of the fetus are important to know to interpret gases after delivery. During the course of normal labor, the PaO_2 drops, the PaCO_2 rises, and the base deficit rises. Severe acidemia is when the pH is below 7 and there is a base deficit of more than 12 mmol/L. Metabolic acidosis in isolation also proved to be a poor predictor of significant perinatal brain injury. The sensitivity and positive predictive value of a low pH for adverse outcome are 21% and 8%, respectively.³

Incidence

Each year 4 million neonates in the world die due to asphyxia which represents 38% of all deaths under 5 years. The frequency of perinatal asphyxia is approximately 1 to 1.5% of live births in western hemisphere and is inversely related to gestational age and birth weight. It occurs in 0.5% of live born infants >36 weeks gestation and accounts for 20% of perinatal deaths. According to the National Neonatal Perinatal Database of India,⁴ 23% of all neonatal deaths in our country are related to asphyxia. Twenty-five to thirty percent of all stillbirths occur intrapartum. In absolute numbers, this translates into between 2,50,000 and 3,50,000 deaths due to asphyxia and contributes to as many as 300,000 to 400,000 stillbirths annually. To add to this, there is an accounted disability related to asphyxia in the developing countries. Because of the limited availability of data, and despite its enormous magnitude, available figures are likely to underestimate the real proportion of the problem.

Clinical Manifestations of HIE

There is multiorgan involvement in the birth asphyxia and neurological involvement is the hallmark of the birth asphyxia. Hypoxic-ischemic encephalopathy (HIE) is characterized by clinical and laboratory evidence of acute or subacute brain injury due to lack of blood supply and oxygen.

Birth to 12 hours: In the first hours after the insult, signs of presumed bilateral cerebral hemispherical disturbance predominate. The severely affected infant is either deeply stuporous or in coma. Periodic breathing or respiratory irregularity is prominent. Severely affected ones may exhibit marked hypoventilation or respiratory failure. Majority of infants at this stage are markedly hypotonic with minimal spontaneous or elicited movement. Less affected ones, have preserved tone and is more likely with prominent involvement of basal ganglia.

12 to 24 hours after insult: During this time the infants neurological status changes in a variable manner. Infants with severe disease remain stuporous and those with less severe disease often begin to exhibit some degree of improvement in alertness. Infants with injury to basal ganglia often exhibit an increase in their hypertonia, especially in response to their handling. Full term infants often exhibit weakness in the hip shoulder distribution, with more impressive involvement of proximal extremities. Seizures often occur during this time.

24 to 72 hours: During this time, the severely affected infant's level of consciousness often deteriorates further and deep stupor or coma ensues. Babies who die with HIE most often do so at this time. Preterm babies may have intraventricular hemorrhages, and term babies often demonstrate signs of major cerebral necrosis.

After 72 hours: Infants who survive to this extent usually improve over the next few days or weeks. Although the level of consciousness improves, mild-to-moderate stupor continues. Disturbances of feeding are common. Generalized hypotonia is common but hypertonia may be seen in babies who have had significant basal ganglia involvement.

Grading of HIE

In 1976, Sarnat and Sarnat (Table 1) published a combined clinical and EEG study of 21 term infants who displayed evidence of fetal distress.⁵ They described a syndrome of neurological and electroencephalogram (EEG) features that they labeled neonatal encephalopathy following fetal distress.

In their original study, the syndrome was divided into three stages, with severely affected infants typically progressing from grades 1 to 3.

This scheme was later modified by Fenichel et al⁶ (Table 2), who grouped the clinical features of what he termed *hypoxic ischemic encephalopathy* (HIE) into three different patterns (mild, moderate and severe). The asphyxiated infant was not considered to progress through the grades but rather to exhibit the characteristic features and time course (of either deterioration or resolution) consistent with a particular grade.

Table 1: Sarnat clinical stages of perinatal hypoxic-ischemic brain injury

	<i>Stage 1</i>	<i>Stage 2</i>	<i>Stage 3</i>
Level of consciousness	Hyperalert	Lethargic or obtunded	Stuporous
Neuromuscular control			
Muscle tone	Normal	Mild hypotonia	Flaccid
Posture	Mild distal flexion	Strong distal flexion	Intermittent decerebration
Stretch reflexes	Overactive	Overactive	Decreased or absent
Segmental myoclonus	Present	Present	Absent
Complex reflexes			
Suck	Weak	Weak or absent	Absent
Moro	Strong; low threshold	Weak; incomplete; high threshold	Absent
Oculovestibular	Normal	Overactive	Weak or absent
Tonic neck	Slight	Strong	Absent
Autonomic function	Generalized sympathetic	Generalized parasympathetic	Both systems depressed
Pupils	Mydriasis	Miosis	Variable; often unequal; poor light reflex
Heart rate	Tachycardia	Bradycardia	Variable
Bronchial and salivary secretions	Sparse	Profuse	Variable
GI motility	Normal or decreased	Increased; diarrhea	Variable
Seizures	None	Common; focal or multifocal	Uncommon (excluding decerebration)
EEG findings	Normal (awake)	Early: low-voltage continuous delta and theta Later: periodic pattern (awake) Seizures: focal 1-to 1-Hz spike-and-wave	Early: periodic pattern with isopotential phases Later: totally isopotential
Duration	1-3 days	2-14	Hours to weeks

Table 2: Fenichel grading for hypoxic-ischemic encephalopathy. The features in the bold are the main requirements for each grade. Features not in bold may be present but are essential for syndrome assignment. a/ b: either abnormal tone or abnormal suck should accompany altered conscious level to assign grade 1

<i>Features</i>	<i>Grade 1 (Mild)</i>	<i>Grade 2 (Moderate)</i>	<i>Grade 3 (Severe)</i>
Conscious level	Irritable/ Hyperalert	Lethargic	Comatose
Tone	Either^aMildly abnormal (hypo/hyper)	Moderately abnormal (Hypotonic or dissociated)	Severely abnormal (Hypotonia)
Suck	Or ^b abnormal	Poor	Absent
Primitive reflexes	Exaggerated	Depressed	Absent
Seizures	Absent	Present	Present
Brainstem reflexes	Normal	Normal	Impaired
Respiration	Tachypneic	Occasional apneas	Severe apnea

For usage in clinical studies and for well equipped centers, Sarnat and Sarnat staging is mostly used but Fenichel grading may be of use in resource constrained settings since it is based only on clinical criteria alone.

Other organ systems⁷ involved following a hypoxic-ischemic events include the following:

1. **Heart (43-78%):** May present as reduced myocardial contractility, severe hypotension, passive cardiac dilatation, and tricuspid regurgitation.
2. **Lungs (71-86%):** Patients may have severe pulmonary hypertension requiring assisted ventilation.
3. **Renal (46-72%):** Renal failure presents as oliguria and, during recovery, as high-output tubular failure, leading to significant water and electrolyte imbalances.
4. **Liver (80-85%):** Elevated liver function test results, hyperammonemia, and coagulopathy can be seen. This may suggest possible GI dysfunction. Poor peristalsis and delayed gastric emptying are common; necrotizing enterocolitis is rare. Intestinal injuries may not be apparent in the first few days of life or until feeds are initiated.
5. **Hematologic (32-54%):** Disturbances include increased nucleated RBC's, neutropenia or neutrophilia, thrombocytopenia, and coagulopathy.

Differential diagnosis of neonatal encephalopathy:

These include: i. perinatal hypoxia-ischemia; ii. hypoglycemia; iii. infection; iv. severe hyperbilirubinemia; v. cerebral trauma; vi. intracranial hemorrhage; vii. idiopathic cerebral infarction; viii. inherited metabolic disorders; ix. congenital neuromuscular disease; and x. congenital dysmorphic syndromes.

Pathophysiology^{8,9} (Fig. 1)

Brain hypoxia and ischemia due to systemic hypoxemia, reduced cerebral blood flow (CBF), or both are the primary physiological processes that lead to hypoxic-ischemic encephalopathy. The initial compensatory adjustment to an asphyxial event is an increase in CBF due to hypoxia and hypercapnia. This is accompanied by a redistribution of cardiac output to essential organs, including the brain, heart, and adrenal glands. With prolonged asphyxial insult and failure of compensatory mechanisms, cerebral blood flow falls, leading to ischemic brain injury. In adults, CBF is maintained at a constant level despite a wide range in systemic BP. This phenomenon is known as the cerebral autoregulation, which helps maintain cerebral perfusion. In human adults, the BP range at which CBF is maintained is 60 to 100 mm Hg.

Data in the human fetus and the newborn infant suggest that CBF is stable over much narrower range of BPs, CBF autoregulation is maintained may be only between 10 to 20 mm Hg (compared with the 40 mm Hg range in adults noted above). In the fetus and newborn suffering from acute asphyxia, after the early compensatory

adjustments fail, the CBF can become pressure-passive, at which time brain perfusion depends on systemic BP. As BP falls, CBF falls below critical levels, and the brain injury secondary to diminished blood supply and a lack of sufficient oxygen occurs. This leads to intracellular energy failure which is also known as *primary energy failure*.

Primary Energy Failure

During the early phases of brain injury, a large cascade of events follows hypoxic-ischemic encephalopathy injury which includes:

- Excitatory amino acid (EAA) receptor overactivation
- Impaired uptake of glutamate
- These result in high synaptic levels of glutamate and EAA receptor overactivation, including N-methyl-D-aspartate (NMDA), amino-3-hydroxy-5-methyl-4 isoxazole propionate (AMPA), and kainate receptors.
- NMDA receptors are permeable to Ca^{++} and Na^+ , whereas AMPA and kainate receptors are permeable to Na^+ . Accumulation of Na^+ coupled with the failure of energy dependent enzymes such as Na^+/K^+ -ATPase leads to rapid cytotoxic edema and necrotic cell death.
- Consequences of increases intracellular Ca^{++} concentration include activation of phospholipases, endonucleases, proteases, and, in select neurons, nitric oxide synthase (NOS). Activation of phospholipase A2 leads to release of Ca^{++} from the ER via activation of phospholipase C. Activation of proteases and endonucleases results in cytoskeletal and DNA damage.

Reperfusion Energy

During the reperfusion period, free radical production increases due to activation of enzymes such as cyclooxygenase, xanthine oxidase, and lipoxygenase. Free radical

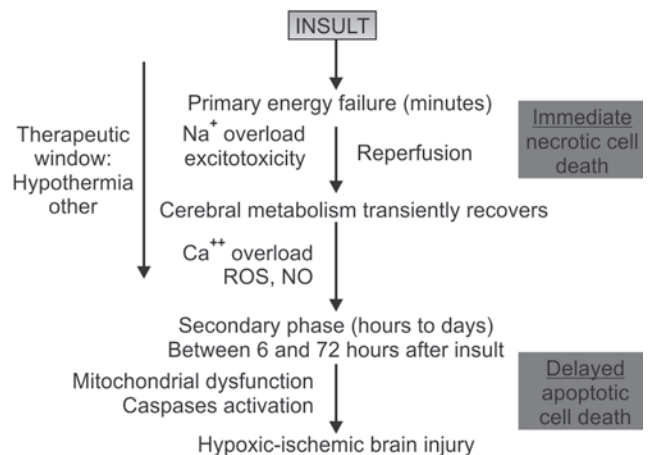

Fig. 1: Pathophysiology of hypoxic-ischemic brain injury in the developing brain. During the initial phase of energy failure, glutamate mediated excitotoxicity and Na^+/K^+ -ATPase failure lead to necrotic cell death. After transient recovery of cerebral energy metabolism, a secondary phase of apoptotic neuronal death occurs. ROS = Reactive oxygen species

damage is further exacerbated in the neonate because of immature antioxidant defenses. Free radicals can lead to lipid peroxidation as well as DNA and protein damage and can trigger apoptosis. Finally, free radicals can combine with nitric oxide (NO) to form peroxynitrite a highly toxic oxidant. NO production plays an important role in the pathophysiology of perinatal hypoxic-ischemic brain injury.

Secondary Energy Failure

Following the initial phase of energy failure from the asphyxial injury, cerebral metabolism may recover following reperfusion, only to deteriorate in a secondary energy failure phase. This new phase of neuronal damage, starting at about 6 to 24 hours after the initial injury, is characterized by mitochondrial dysfunction, and initiation of the apoptotic cascade. This phase has been called the “delayed phase of neuronal injury”. The duration of the delayed phase is not precisely known in the human fetus and newborn but appears to increase over the first 24 to 48 hours and then starts to resolve thereafter.

LABORATORY STUDIES

These are nonspecific tests to confirm or exclude a diagnosis of hypoxic-ischemic encephalopathy (HIE) because the diagnosis is made based on the history, physical and neurological examinations, and laboratory evidence. Many of the tests are performed to assess the severity of brain injury and to monitor the functional status of systemic organs. As always, the results of the tests should be interpreted in conjunction with the clinical history and the findings from physical examination.

Laboratory Studies should Include the Following

Serum Electrolyte Levels and Renal Function Test

In severe cases, daily assessment of serum electrolytes is valuable until the infant's status improves. Markedly low serum sodium, potassium, and chloride levels in the presence of reduced urine flow and excessive weight gain may indicate acute tubular damage or syndrome of inappropriate antidiuretic hormone (SIADH) secretion, particularly during the initial 2 to 3 days of life. Serum creatinine levels, creatinine clearance, and BUN levels suffice in most cases.

Cardiac and Liver Enzymes

These values are an adjunct to assess the degree of hypoxic-ischemic injury to these other organs. These findings may also provide some insight into injuries to other organs, such as the bowel.

Blood Gas Monitoring

Blood gas monitoring is used to assess acid-base status and to avoid hyperoxia and hypoxia as well as hypercapnia and hypocapnia.

Neuroimaging

Neuroimaging has become increasingly important in the evaluation of neonatal encephalopathy, and may provide information regarding the type and timing of brain injury. Various modalities have been used to evaluate infant brains with neonatal encephalopathy, including cranial sonography (CS), computed tomography (CT) and magnetic resonance imaging (MRI) with MR spectroscopy. Head MR imaging techniques yield the most useful information, though the resources necessary for transporting, monitoring, and supporting sick babies during this procedure are not always readily available.

Cranial sonography: Head sonography has a low sensitivity (50%) for the detection of anomalies associated with hypoxic-ischemic encephalopathy. Findings include global increase in cerebral echogenicity and obliteration of cerebrospinal fluid (CSF) containing spaces suggestive of cerebral edema. Increase in the echogenicity of deep gray matter structures may also be identified, typically when ultrasonography is performed after 7 days of life. Cranial sonography has a high sensitivity and specificity for locating hemorrhages and defining ventricular size.

Head CT: CT scan of the head can be useful to confirm cerebral edema (obliteration of cerebral ventricles, blurring of sulci), manifested as narrowness of the lateral ventricles and flattening of gyri. Areas of reduced density that indicate evolving zones of infarction may be present. Evidence of hemorrhage in the ventricles or in the cerebral parenchyma may also be seen.

Head MRI, MR spectroscopy and diffusion-weighted imaging (DWI) techniques: MRI¹⁰ is the imaging modality of choice for the diagnosis and follow-up of infants with moderate-to-severe hypoxic-ischemic encephalopathy (HIE). Early MRI (and particularly after day 4), conventional images may accurately demonstrate the injury pattern as area of hyperintensity. DWI allows earlier identification of injury patterns in the first 24 to 48 hours. The MRI sequence identifies areas of edema and, hence, injured areas. DWI changes peak at 3-5 day and pseudonormalizes by the end of the first week. MRS allows for quantification of intracellular molecules. Proton MRS allows identification of cerebral lactate, which persist for weeks following a significant hypoxic-ischemic injury.

Electroencephalography

Amplitude-integrated electroencephalography (aEEG): Several studies¹¹ have shown that a single-channel aEEG performed within a few hours of birth can help evaluate the severity of brain injury in the infant with hypoxic-ischemic encephalopathy. The abnormalities seen in infants with moderate-to-severe hypoxic-ischemic encephalopathy include the following:

- Discontinuous tracing characterized by a lower margin below 5 mV and an upper margin above 10 mV.
- Burst suppression pattern characterized by a background with minimum amplitude (0-2 mV) without variability and occasional high voltage bursts (>25 mV).
- Continuous low voltage pattern characterized by a continuous low voltage background (< 5 mV).
- Inactive pattern with no detectable cortical activity.
- Seizures, usually seen as an abrupt rise in both the lower and upper margin.

Note that considerable training is required for conducting and properly interpreting the aEEG findings. aEEG can accurately predict poor outcome with a sensitivity of 91% (95% CI, 87-95).

Standard EEG

Traditional, multichannel EEG is an integral part of the evaluation of infants diagnosed with hypoxic-ischemic encephalopathy. It is a valuable tool to assess the severity of the injury and evaluate for subclinical seizures.

Generalized depression of the background rhythm and voltage, with varying degrees of superimposed seizures, are early findings. EEG characteristics associated with abnormal outcomes include:

- Background amplitude of less than 30 mV.
- Interburst interval of more than 30 seconds.
- Electrographic seizures.
- Absence of sleep-wake cycle at 48 hours.

Serial EEGs should be obtained to assess seizure control and evolution of background abnormalities. Improvement in the EEG findings over the first week, in conjunction with improvement in the clinical condition, may help predict a better long-term outcome.

TREATMENT

Following initial resuscitation and stabilization, treatment of hypoxic-ischemic encephalopathy (HIE) is largely supportive. Delivery room management follows standard Neonatal Resuscitation Program (NRP) guidelines. Close attention should be paid to appropriate oxygen delivery, perfusion status, and avoidance of hyperthermia. All babies with neonatal asphyxia should be admitted in a neonatal intensive care unit. Major goals include:

- Maintenance of physiologic homeostasis
- Neuroprotective therapeutic measures.

Maintenance of Physiologic Homeostasis

Central aspects of supportive care include the following:

- Maintenance of adequate ventilation:* Avoidance of hypoxemia, hyperoxia, hypercapnia, and hypocapnia. Hypocapnia in particular may lead to severe brain hypoperfusion and cellular alkalosis and has

been associated with worse neurodevelopmental outcomes.

- Maintenance of sufficient brain and organ perfusion (avoidance of systemic hypotension or hypertension; avoidance of hyperviscosity):* Mean blood pressure (BP) above 35 to 40 mm Hg is necessary to avoid decreased cerebral perfusion. Hypotension is common in infants with severe hypoxic-ischemic encephalopathy and is due to myocardial dysfunction, capillary leak syndrome, and hypovolemia; hypotension should be promptly treated. Dopamine or dobutamine can be used to achieve adequate cardiac output in these patients.
- Fluid and electrolytes management:* Because of the concern for acute tubular necrosis (ATN) and syndrome of inappropriate antidiuretic hormone (SIADH) secretion, fluid restriction is typically recommended for these infants until renal function and urine output can be evaluated. Therefore, fluid and electrolyte management must be individualized on the basis of clinical course, changes in weight, urine output, and the results of serum electrolyte and renal function studies. Avoidance of fluid overload is critical to prevent brain edema.
- Maintenance of normal metabolic status (e.g. normoglycemia, nutritional status, pH):* Avoid hypoglycemia and hyperglycemia because both may accentuate brain damage. Initial hypoglycemia (<40 mg/dL) is significantly associated with adverse neurological outcomes. Arterial blood gases and serum calcium, magnesium, glucose, and electrolytes should be assessed early in the course and as needed.
- Avoid hyperthermia:* It has been shown to be associated with increased risk of adverse outcomes in neonates with moderate-to-severe hypoxic-ischemic encephalopathy. In one observational study,¹² the risk of death or moderate-to-severe disability was increased 3.6-fold to 4-fold for every 1°C increase in the mean of the highest quartile of skin or esophageal temperature.
- Control of seizures:* HIE is the most common cause of seizures in the neonatal period. Studies suggest that seizures, including asymptomatic electrographic seizures, may contribute to brain injury and increase the risk of subsequent epilepsy. Current therapies available to treat neonates with seizures include phenobarbital, phenytoin, and benzodiazepines. Phenobarbital has been shown to be effective in only 29 to 50% of cases. Phenytoin only offers an additional 15% efficacy. Benzodiazepines, particularly lorazepam, may offer some additional efficacy.

Neuroprotective Therapeutic Measures

Including therapeutic hypothermia or other potential neuroprotective measures.

Therapeutic Hypothermia

Extensive experimental data suggest that mild hypothermia (3-4°C below baseline temperature) applied within a few hours (no later than 6 h) of injury is neuroprotective. The neuroprotective mechanisms are not completely understood. Possible mechanisms include:

1. Reduced metabolic rate and energy depletion.
2. Decreased excitatory transmitter release.
3. Reduced alterations in ion flux.
4. Reduced apoptosis due to hypoxic-ischemic encephalopathy.
5. Reduced vascular permeability, edema, and disruptions of blood-brain barrier functions.

Therapeutic hypothermia compared with usual care was associated with a significant reduction in the combined primary endpoint of death or moderate to severe neurodevelopmental disability. Hypothermia is the only effective neuroprotective therapy currently available for treatment of HIE and is safe and easy to administer. The clinical efficacy of therapeutic hypothermia in neonates with moderate-to-severe hypoxic-ischemic encephalopathy has been evaluated in seven randomized controlled trials.¹³⁻²⁰ Inclusion criteria varied slightly. Criteria from the larger trials (NICHD, CoolCap, and TOBY) are summarized as follows:

- Near-term infants born at 36 weeks' gestation or more with birth weight of 1800 to 2000 g or more, younger than 6 hours at admission.
- Evidence of acute event around the time of birth:
 - Apgar score of 5 or less at 10 minutes after birth
 - Severe acidosis, defined as pH level of less than 7 or base deficit of 16 mmol/L or less (cord blood or any blood gas obtained within 1 h of birth)
 - Continued need for resuscitation at 10 minutes after birth.
- Evidence of moderate to severe encephalopathy at birth: At least two of the following:
 - Lethargy, stupor, or coma
 - Abnormal tone or posture
 - Abnormal reflexes [suck, grasp, Moro, gag, stretch reflexes]
 - Decreased or absent spontaneous activity
 - Autonomic dysfunction [including bradycardia, abnormal pupils, apneas]
 - Clinical evidence of seizures.
- Moderately or severely abnormal amplitude-integrated electroencephalography (aEEG) background or seizures (CoolCap and TOBY).

Many theoretical concerns surround hypothermia and its side effects, which include coagulation defects, leukocyte malfunctions, and pulmonary hypertension, worsening of metabolic acidosis, and abnormalities of cardiac rhythm, especially during rewarming. Although all these trials suggest, cooling is well tolerated and not associated with any increase in death or serious adverse events.

Several meta-analysis have been conducted and indicate that that therapeutic hypothermia is beneficial to term newborns with hypoxic-ischemic encephalopathy.

- In a Cochrane review,²¹ Jacobs et al found that therapeutic hypothermia results in significant reduction in the following: Combined outcome of mortality or major neurodevelopmental disability at age 18 months [relative risk (RR), 0.76; 95% confidence interval (CI), 0.65-0.89], with a number needed to treat (NNT) of 7 (95% CI, 4-14).
- Meta-analysis by Schulzke et al²² concluded that significant benefit of hypothermia on the composite outcome of death or disability (RR, 0.78; 95% CI, 0.66-0.92) with an NNT of 8 (95% CI: 5-20).

PROCEDURE OF HYPOTHERMIA

Indication: As above

Initiation time: Cooling must begin early, within 6 hours of injury. However, experimental evidence strongly suggest that the earlier the better.

Duration of hypothermia therapy: The optimal duration of brain cooling in the human newborn has not been established. In most of the clinical trials, it is for 72 hours.

Methods:

Two methods have been used in clinical trials:

- Selective head cooling
- Whole body cooling.

In selective head cooling, a cap (CoolCap) with channels for circulating cold water is placed over the infant's head, and a pumping device facilitates continuous circulation of cold water. Nasopharyngeal or rectal temperature is then maintained at 34 to 35°C for 72 hours.

In whole body hypothermia, a cooling blanket wrapped around the baby is necessary for keep the core temperature in the desired range.

The relative merits and limitations of these two methods have not been established.

In resource constrained setting like ours, few feasibility trials of achieving hypothermia with ice packs have been tried but those have to undergo rigorous safety studies to test their efficacy and safety.

Rewarming Method

Rewarming is a critical period. In clinical trials, rewarming was carried out gradually, over 6 to 8 hours.

PROGNOSIS

Clinical criteria which suggest bad prognosis are:

- *Urine output:* If an infant had good urine output, the chances of mortality and neurologic injury are 5% and 10%, respectively, whereas oliguria beyond 24 hours

resulted in rates of mortality and neurologic injury of 33% and 67%, respectively.²⁵ Acute tubular necrosis has not been shown to be of good prognostic value.

- *Severity and duration of encephalopathy:* Grading schemes for the severity of HIE have been used as predictors of long-term neurological function. Almost all infants with mild encephalopathy have a good outcome. The outcome of infants with moderate encephalopathy is less predictable and up to 75% of infants may make a normal recovery. Persistence of stage 2 for more than 7 days or stage 3 at any time is associated with later neurologic impairment or death.²⁶ When the neurologic syndrome was severe, 80% of infants died and the remaining 20% had significant sequel.
- *Persistent seizures:* If the seizures are persistent or recalcitrant to anticonvulsant medications, they are nearly uniformly associated with death or significant neurologic deficits.
- *Discharge neurological examination:* If a newborn's neurologic examination returns to normal by 1 to 2 weeks, the infant likely will be normal at follow-up.

Laboratory finding which suggest poor prognosis:

- *EEG:* EEG has proved to be a more reliable predictor of outcome than the early neurological examination. Conventional and amplitude integrated EEG has been used to predict long-term neurological outcome in asphyxiated infants. At any time, a burst-suppression (especially when it is unresponsive to stimuli) or an isoelectric pattern is associated with poor outcome. If there is only mild depression early, there can be normal outcome. If there is depression after 12 days, poor outcome is expected. A normal EEG at 7 days predicts normal outcome.
- *CT scan:* Presence of cystic encephalomalacia on follow-up at 3 to 4 weeks on CT scan is suggestive of a very poor outcome.
- *MRI imaging:* The optimal timing of MRI scans for maximal prognostic power remains unresolved. This is in large part because of the natural evolution of brain tissue injury and its changing appearance on MRI studies. Because cerebral edema usually peaks around 3 days after birth and gradually resolved over the subsequent week, some authors have favored MRI studies at 72 hours for prognostic purposes. Specifically, a normal MRI scan at 72 hours is predictive of a favorable outcome where as diffuse edema with impaired cortical gray white differentiation or lesions in the dorsolateral thalamus or dorsal putamen are reliable predictors of poor outcome. When deep nuclear lesions occur in combination with brainstem injury, the outcome is particularly poor, with prominent disturbances in speech, sucking and swallowing.

Follow-up: Close physical therapy and developmental evaluations are needed prior to discharge in patients with birth asphyxia. The goal of follow-up is to detect impairments and promote early intervention for those infants who require it.

CONCLUSION

Hypothermia therapy should be conducted under strict protocols and reserved to regional referral centers offering comprehensive multidisciplinary care and planning to conduct long-term neurodevelopmental follow-up. Therapeutic hypothermia compared with usual care was associated with a significant reduction in the combined primary endpoint of death or moderate to severe neurodevelopmental disability. Hypothermia is the only effective neuroprotective therapy currently available for treatment of HIE and is safe and easy to administer.

Future prospects—A variety of potential neuroprotective treatments are being studied both to prevent the cascade of injurious effects after hypoxia-ischemia.

- *Erythropoietin:* In a recent study,²³ low-dose erythropoietin (300-500 U/kg) administered for 2 weeks starting in the first 48 hours of life decreased the incidence of death or moderate and severe disability at age 18 months (43.8% vs 24.6%; $P < 0.05$) in infants with moderate-to-severe hypoxic-ischemic encephalopathy.
- *Prophylactic barbiturates:* In a small randomized trial,²⁴ high-dose phenobarbital (40 mg/kg) was given over 1 hour to infants with severe hypoxic-ischemic encephalopathy. Treated infants had fewer seizures (9 of 15) than untreated control infants (14 of 16). Treated infants also had fewer neurological deficits at age 3 years (4 of 15) than untreated infants (13 of 16). Meta analysis on the use of anticonvulsants in perinatal asphyxia did not show any significant benefit of using prophylactic phenobarbitone and also in experimental animals phenobarbitone has been shown to causes apoptosis of brain cells during asphyxia. Hence at the current moment, phenobarbitone should be used for prophylactic reasons.
- *Allopurinol:* Slight improvements in survival and cerebral blood flow (CBF) were noted in a small group of infants tested with this free-radical scavenger in one clinical trial. Currently a multicentric trial called the ALLO-Trial is going on to document the efficacy of allopurinol in decreasing birth asphyxia when given to the mother.
- *Excitatory amino acid (EAA) antagonists:* MK-801, an EAA antagonist, has shown promising results in experimental animals and in a limited number of adult trials.
- Administration of growth factors (monosialo-gangliosides, brain derived growth factor), nitric oxide synthase inhibitors, and blockers of apoptosis.

CHAPTER 10

Neonatal Seizures

RG Holla

INTRODUCTION

A seizure is defined clinically as a paroxysmal alteration in neurologic function, i.e. motor, behavior and/or autonomic function. Neonatal seizures constitute a medical emergency and clinicians caring for neonates with seizures are inevitably faced with questions regarding diagnosis, evaluation, management and outcome. Although, controversies exist in the diagnosis of neonatal seizures, once the diagnosis is made, these babies have significant mortality and risk for major neurodevelopmental disability. The immature neonatal brain has a limited repertoire of clinical manifestations. This developmental characteristic has bearing on the etiology, clinical, electrographic features and management of neonatal seizures. Since, EEG correlation of seizures is not always available and clinical features are often atypical and dependant on individual interpretation, management options need to be carefully considered before they are instituted. Most neonatal seizures occur over only a few days, and fewer than half of affected infants develop seizures later in life.

BIOCHEMICAL BASIS OF SEIZURES

Seizures occur when a large group of neurons undergo excessive, synchronized depolarization. The arborization of axons and dendritic processes as well as myelination are incomplete in the neonatal brain, resulting in weakly propagated, fragmentary seizures, whose electrical activity may not spread to surface EEG electrodes. Seizure threshold is determined by the interplay of excitatory vs. inhibitory neurotransmitter systems. The immature brain is more prone to seizures than the mature brain because of a developmental mismatch between excitation and inhibition. GABA (gamma-amino-butyric acid) is the principal inhibitory neurotransmitter and glutamate is the excitatory neurotransmitter.

RECEPTORS IN THE BRAIN

GABA(A) receptor is a transmembrane receptor located at the neuronal membrane which causes chloride ions to move down an electrochemical gradient, leading to hyperpolarization of the neuron, increase in the firing threshold and reduction in the action potential initiation. Increased chloride permeability can, however, depolarize the neuron under conditions of high intracellular chloride, a situation that exists in the neonatal period. This, in turn, can potentially excite the cell to fire or to activate calcium entry via voltage gated channels, leading to persistent depolarization. Certain ligands interact with the GABA(A) receptor to mimic GABA or to potentiate its response. These include benzodiazepines (increase pore opening frequency), barbiturates (increased pore opening duration), and certain steroids. Other compounds which interact with the GABA(A) receptor to attenuate the effects of GABA are flumazenil (a competitive benzodiazepine antagonist) and picrotoxin, which blocks the channel directly.

The GABA(B) receptor is metabotropic, coupled indirectly to potassium channels and causes an efflux of potassium from the neuron and suppresses action potential. GABA(B) receptors can mediate both post- and presynaptic inhibition.

In the newborn, the GABA system is functionally immature and characterized by decreased binding and uptake of GABA by receptors.¹ Interestingly, it has been found that the response to GABA(A) can be excitatory or inhibitory depending on the age, region of the brain studied and also upon the sex of the newborn animal.² In newborn rats, GABA has been found to have excitatory effects as immature neurons have high chloride content. The other major postsynaptic inhibitory system, the postsynaptic GABA(B), adenosine, and 5 hydroxytryptamine-G

protein coupled potassium channels, also have a delayed maturation.

The excitatory neurotransmitter, glutamate acts through the n-methyl-d- aspartate (NMDA), alpha-amino-3-hydroxy-5-methylisoxazole-4-proiponic acid (AMPA) and kainite (KA) receptors. In adults, the sequence of events for neuronal transmission consists of AMPA stimulation (leading to sodium entry), activation of NMDA channels and subsequent calcium entry into the cell, followed by postsynaptic inhibition by GABA. In the neonate, AMPA and postsynaptic GABA receptors are underdeveloped. This, coupled with the excitatory nature of presynaptic GABA receptors leads to a situation in which there is poor transmitter-gated inhibition, creating a milieu in which seizures are easily elicited.

EFFECTS OF SEIZURES ON THE NEONATAL BRAIN

The immature brain is more susceptible to epileptiform activity than its more mature counterpart. Although the immature brain is less vulnerable than the mature brain to seizure induced cell death, seizures in the developing brain can result in irreversible alterations in neuronal connectivity.

Seizures, particularly those that are prolonged, stress the neurons ability to generate energy necessary for cell function. Mitochondria which subserve this metabolic function produce reactive oxygen species during seizures, which then initiate excitotoxic injury by altering calcium homeostasis and energy production.

Seizures also affect the brain in other ways. Both electroclinical and electrographic (without overt clinical features) neonatal seizures produce an increase in cerebral blood flow velocity which is not related to an increase in blood pressure associated with the seizure.³ Regional hyperperfusion during clinical or EEG seizures has been reported on SPECT in neonates.⁴ This can adversely affect cerebral autoregulation in sick neonates. Experimental evidence also suggests that enhanced neuronal firing by itself, even without clinical seizures inhibits protein synthesis and causes cell damage. In newborn rats, seizures inhibit brain protein synthesis, reduced brain size and delayed developmental milestones.⁵ It is known that brain growth continues postnatally and mitotic activity continues in the human cerebellum during the first year of life, lending a unique vulnerability to the neonatal brain.

Alongside the increased vulnerability of the immature brain to seizures is the relative resistance to seizure induced excitotoxic damage when compared with adult counterparts. Although several hypotheses have been proposed, no consensus exists as to the mechanism of this neuroprotection. A family of mitochondrial uncoupling proteins (UCPs) which dissociate ATP production from oxygen consumption by reducing the membrane potential across the mitochondrial membrane, reducing the production of free oxygen reactive species has been proposed.

Higher levels of UCP have been reported in the neonatal brain.⁶

ETIOLOGY

Perinatal Asphyxia

Perinatal asphyxia is the single most important cause of neonatal seizures.⁷ Asphyxia insult may occur before, during or after the intrapartum period, the last accounting for about 10 percent of the cases. Seizures frequently present within the first 72 hours of life and may include subtle, clonic or generalized seizures. Intrauterine risk factors for asphyxia are related to poor placental transfer of oxygen and/or glucose due to pre-eclampsia, uteroplacental abnormalities such as abruption placentae, cord compression or placental insufficiency. Vascular insufficiency may also occur due to chorioamnionitis, antepartum trauma and meconium passage *in utero*. Using logistic regression analysis, Patterson et al identified antepartum anemia, antepartum bleeding, asthma, meconium-stained amniotic fluid, malpresentation, fetal distress and shoulder dystocia as risk factors for seizures in the first 72 hours in term neonates.⁸ Other risk factors include failure to use prophylactic antibiotics for antepartum infection, non-reassuring fetal heart rate patterns and lack of antepartum monitoring.⁹ It should be stressed that normal Apgar scores do not eliminate the possibility of severe intrauterine brain injury from asphyxia or other causes. As many as two-thirds of neonates who exhibit cerebral palsy at older ages had normal apgars at birth.¹⁰ Features of antenatal asphyxia injury in the form of joint contractures, persistent early cortical thumb, intrauterine growth restriction, etc. should be looked for.

Severe hypoxic insults can result in frequent seizures in the first week of life despite multiple medications at supratherapeutic dosages.

Hypocalcemia and Hypomagnesemia

Hypocalcemia may be associated with seizures, and may manifest at two distinct stages of the neonate's life as early or late hypocalcaemia. Early hypocalcemia (generally presents within 48 to 72 h after birth) may be accompanied by other epileptogenic situations such as hypoxic ischemic encephalopathy which may contribute to the seizure.¹¹ The outlook for neonates with seizures due to late onset hypocalcemia is generally good. Apart from the use of phosphate rich formula feeds, maternal hypovitaminosis D is an important cause of hypocalcemia in the neonate.

Hypoglycemia

Defined as a blood sugar level less than 45 mg/dl, hypoglycemia may cause seizures by itself, or in association with other comorbid conditions, e.g. hypocalcemia, hypoxic ischemic encephalopathy, and cranial trauma, which may

lower the threshold for seizures. Inborn errors of metabolism should be sought for in cases of persistent hypoglycemia. Low blood glucose substrate for neuronal metabolism and altered membrane excitability may both contribute to seizures in hypoglycemia. Jitteriness, apnea and altered tone are clinical may be the only clinical sign of hypoglycemia. Defect in glucose transport can also cause hypoglycorrachia and seizures in the absence of low blood glucose levels.

Sodium Disturbances

Hyponatremia (serum sodium less than 135 mmol/L) can occur in a variety of clinical situations in the neonatal intensive care unit. Increased losses, inadequate intake, diuretic use and clinical conditions like necrotizing enterocolitis can be associated with hyponatremia. Hypernatremia or its rapid correction may also be associated with seizures.

Cerebrovascular Lesions

Hemorrhagic and ischemic cerebral lesions are usually associated with seizures. In the preterm neonate, intraventricular hemorrhage is associated with seizures in about half the cases. Subtle seizures are seen frequently with this type of hemorrhage. Other hemorrhagic lesions include subarachnoid, subdural and intracerebral hemorrhages. Subarachnoid hemorrhage is more common in full term infants. The early appearance of neonatal jaundice in a neonate with seizures and abnormal sensorium should alert the clinician to the possibility of intracranial hemorrhage.

Cerebral infarction may occur in the antepartum or postnatal period. Venous infarcts due to lateral or sagittal sinus thrombosis may occur secondary to sepsis, polycythemia and dehydration. Deep white matter infarctions may follow intraventricular hemorrhage or hypocarbia in the preterm neonate.

Infection

Encephalopathy associated with TORCH, enterovirus or parvoviral infections may manifest with seizures. Seizures due to neonatal herpes simplex infection are associated with severe EEG abnormalities. Leptomenigeal inflammation, abscess or cerebrovascular occlusion associated with sepsis may be responsible for seizures.

Malformations

Neonates with lissencephaly, pachygyria and polymicrogyria may manifest seizures in the neonatal period.

Inborn Errors of Metabolism

Neonatal seizures may accompany nonketotic hyperglycinemia, sulfite oxidase deficiency, multiple carboxylase

deficiency and urea cycle disorders. Diagnostic work-up should include blood gas analysis, serum ammonia and blood sugar estimation. Zellweger syndrome and neonatal adrenoleukodystrophy are associated with high levels of very long chain fatty acids and characteristic findings on MRI. In pyridoxine dependency, low levels of pyridoxal phosphate, the active form of pyridoxine lead to inadequate synthesis of GABA, resulting in severe, resistant, early neonatal (and often fetal) seizures. The diagnosis is established by the administration of 50 to 100 mg of pyridoxine intravenously.

Drug Induced Seizures

Drugs such as barbiturates, alcohol, heroin, cocaine and methadone can cause irritability and seizures during withdrawal, as occurs in infants of mothers addicted to these substances. Inadvertent injection of local anesthetic agent into the fetal scalp during par cervical block can cause refractory seizures.

Epileptic Syndromes

Primary epileptic syndromes such as Ohtahara syndrome generally present beyond the neonatal period and are associated with myoclonic seizures and cerebral malformations (e.g. Aicardi syndrome or porencephaly). Other disorders to be excluded are neurocutaneous syndromes, including incontinentia pigmenti and tuberous sclerosis.

Familial Neonatal Seizures

Benign familial neonatal convulsions constitute a rare disorder with autosomal dominant inheritance of abnormality in the voltage gated potassium channel genes located at *20q13.3* and *8q24*. Seizures generally occur on the second or third day of life in otherwise healthy neonates and tend to persist. They are mainly clonic, sometimes with apneic spells; tonic seizures have rarely been described, the outcome is favorable, but secondary epilepsy may occur in 10 to 15 percent. Diagnosis is by exclusion of other etiologies and should include a work-up for infectious, metabolic and structural abnormalities.

Benign Neonatal Seizures

Benign idiopathic neonatal convulsions occur around the fifth day of life (day 1 to day 7, with 90% between day 4 and 6) in otherwise healthy neonates. Seizures are often multifocal clonic. The diagnosis is one of exclusion. Seizures usually resolve by 24 hours. The outcome is good, but increased risk of minor neurological impairment has been reported.

CLINICAL FEATURES AND CLASSIFICATION

Normal neonatal behavior can at times consist of stereotypic movements under normal circumstances or when

the neonate is under the effect of medications. Ideally, therefore, all suspected seizures should be confirmed by electroencephalography (EEG), keeping in mind, subcortical seizures may not have typical findings on the EEG.

The rarity of generalized tonic-clonic seizures in the neonate are related to the anatomical and physiological immaturity of the neonatal nervous system such as incomplete myelination which prevents highly organized, synchronous seizure activity.

The clinical classification of neonatal seizures has traditionally subdivided seizures into subtle, clonic, tonic and myoclonic.

Clonic seizures are characterized by rhythmic, repetitive movements of isolated parts of the body.

Focal clonic seizures involve one body part.

Multifocal clonic seizures involve several parts of the body simultaneously or in sequence with migration in a random fashion.

Myoclonic seizures represent very brief isolated jerks of parts of the body.

Tonic seizures involve stiffening of parts of the body and may be generalized or focal.

Subtle seizures consist of eye deviation, oral-buccal movements or patterned movements of the extremities like bicycling.

Mizrahi and Kellaway¹² showed that not all such clinical spells in neonates represented seizures. Using video-EEG, it was shown that most clonic seizures, myoclonic seizures and focal tonic seizures had definite epileptiform EEG correlates and thus had a definite epileptic pathogenesis. Generalized tonic seizures, and most forms of subtle seizures, except for isolated eye deviation, did not have any EEG correlate and thus were not felt to be true epileptic seizures. Seizures with no relationship or an inconsistent relationship to EEG seizure activity were correlated to diffuse processes such as hypoxic-ischemic encephalopathy and a poor short-term outcome. The authors proposed that these nonepileptic spells represented abnormal brainstem release reflexes, possibly due to loss of cortical inhibition from cortical damage. The classification proposed by Mizrahi and Kellaway is shown in Table 1.

INVESTIGATIONS

The sizeable differential diagnosis of a neonatal seizure demands that the initial investigations concentrate on the common etiologies requiring prompt treatment. Certain clues to the etiology may be present, such as a history of perinatal asphyxia, but other causes such as hypoglycemia, hypocalcemia and CNS infection may coexist and initial sampling should include a search for these. Laboratory samples to be collected before starting treatment should include blood glucose and serum electrolytes including calcium and magnesium. CSF examination should include a search for xanthochromia, pleocytosis, glucose

Table 1: Etiology of neonatal seizures

S.No	Cause

17.	Congenital infections
18.	Injection of local anesthetic into scalp

and culture. TORCH titers, PCR for herpes virus, lactate, pyruvate and metabolic screen should be performed in the CSF where such conditions are suspected. In the absence of meningitis, a persistently low CSF glucose suggests a glucose transporter defect. Other disorders that require exclusion are inborn errors of metabolism for which arterial blood gas analysis, serum ammonia, amino acid profile, and assessment for organic acidurias. Indirect markers of hypoxia such as azotemia, abnormal liver function tests, and nucleated red blood cells on peripheral smear should be looked for.

Imaging

Each imaging modality available for neonates with seizures vary in terms of level of expertise to perform and interpret, convenience and interpretative quality. Neuroimaging in a case of neonatal seizures may help in diagnosing the etiology of the seizures and measuring the extent of severity of the cerebral insult.

Cranial sonography is a good bedside modality and helps to rule out intracranial hemorrhage, major malformations and abscesses and cerebral edema and should be performed in all sick neonates with seizures. Limitations of neurosonography include its inability to detect subarachnoid and subdural hemorrhage. Serial ultrasound studies are of greater value than a single examination, in both the preterm and term population.

In term infants with seizures with a history of neonatal encephalopathy, significant birth trauma, and evidence of low hematocrit and/or coagulopathy, a noncontrast CT should be performed to look for hemorrhage. In other newborns with encephalopathy or if CT findings are inconclusive, MRI should be performed between days 2 and 8 to assess the location and extent of injury.

In newborns with encephalopathy, CT scans are useful to identify the major pattern of injury on the third day of life while diffusion-weighted MRI is best able to identify cortical abnormalities, stroke or white matter injury. Subsequently (in the second week of life) the extent of cortical injury should be discernible by T₁- and T₂-weighted scans.

Electroencephalography

An electroencephalography may be useful to detect suspect seizures, to prognosticate the outcome, assess the severity of brain dysfunction and to decide the duration of antiepileptic medications.

Neonatal EEG patterns change with postnatal and gestational age and interpretation requires experience. While the EEG is of value in the diagnosis of electrical seizure, pathognomonic features are rarely present. Abnormal patterns include burst suppression, electrocerebral inactivity, low voltage invariant patterns, persistently slow background and multifocal sharp waves on the interictal EEG. Cerebrovascular disease is generally associated with persistent lateralized epileptiform discharges (PLEDs). Ictal patterns include abnormalities of background and focal abnormalities lasting for 10 sec or more.¹³ The duration of seizure patterns varies; status epilepticus in the neonatal period is defined as continuous seizure activity lasting for more than 30 min or 50 percent of the recording time.

Amplitude integrated EEG and cerebral function monitoring: The term amplitude integrated EEG is a method for electrocortical monitoring in which the EEG signal is recorded from one pair of biparietally placed electrodes. The signal is amplified and passed through a filter, which attenuates activity between 2 to 15 Hz in order to minimize artifactual activity from sources such as sweating, muscle activity and electrical interference. The band width in the output reflects variations in minimum and maximum electrical amplitudes, both of which depend on the maturity and severity of the illness. Cerebral function monitor (CFM) is the equipment used to monitor aEEG at the bedside. The normal background pattern consists of a continuous trace with a voltage of 10-25 μ V. Discontinuous traces, bursts and periods of inactivity suggest underlying abnormality. Seizures are recognized as a rapid rise in both upper and lower margins of the trace. Status epilepticus is associated with a "saw toothed" pattern.¹⁴ The advantage of 'aEEG' is its immediate availability, appropriate for bedside long-term monitoring, ease of application and interpretation. While it is not as sensitive in the detection

of seizures as conventional EEG, it is an excellent bedside monitoring tool, particularly in the pharmacologically paralyzed neonate to detect cerebral (and seizure) activity that would be missed clinically and for the prediction of outcome in the neurologically compromised neonate.

DIFFERENTIAL DIAGNOSIS

The most common mimic of seizures is jitteriness, which is a stimulus sensitive tremulousness not associated with gaze abnormalities or autonomic dysfunction and can be suppressed by passive flexion of the limb. Benign neonatal sleep myoclonus is bilateral or unilateral, synchronous or asynchronous myoclonus that occurs during active sleep and is often confused with seizures. Other non-seizure movement disorders seen in neurologically affected newborns include stimulus induced myoclonus and hyper-reflexia (Table 2).

Neonatal seizures may result from a variety of causes, some transient, not associated with structural abnormalities and are to an extent reversible in terms of neurological outcome. The age of the neonate at the onset of neonatal seizures gives a clue to the underlying disorders shown in Table 3 and Flow chart 1.

MANAGEMENT

The general principles of management of neonatal seizures are similar to that in older children, i.e. treatment of the underlying cause and specific management of

Flow chart 1: Management protocol for neonatal seizures

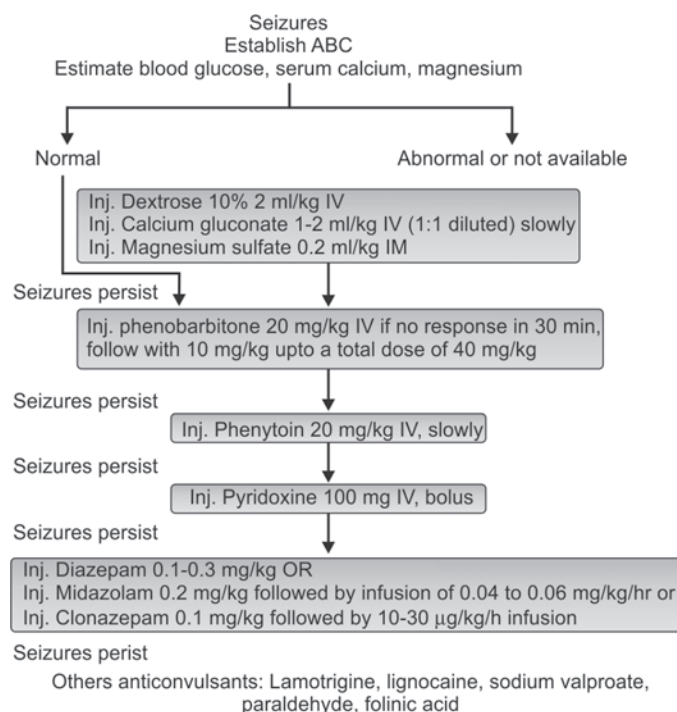

Table 2: Classification and characteristics of neonatal seizures (Modified from scher)

<i>Seizure class</i>		<i>Characterization</i>	<i>Provocation/suppression</i>	<i>Etiology</i>
Focal clonic		Repetitive rhythmic contraction of muscle groups, multi- or unifocal, synchronous or asynchronous	Cannot be suppressed by restraint	Epileptic
Focal tonic		Sustained posturing of single limbs, asymmetric posturing of trunk, sustained eye deviation	Cannot be provoked by stimulation/suppressed by restraint	
Generalized tonic		Sustained symmetrical posturing of trunk, neck, limbs	Provoked/intensified by stimulation, suppressed by restraint/repositioning	Epileptic or nonepileptic
Myoclonic		Random, single, rapid contractions of muscle groups, generalized, focal, fragmentary	Provoked by stimulation	
Spasms		Flexor, extensor, mixed	Cannot be provoked by stimulation/suppressed by restraint	Nonepileptic
Motor automatisms (nonepileptic behavior)	Ocular signs	Random roving eye movements, nystagmus	Provoked/intensified by tactile stimulation	
	Oral-buccal-lingual movements	Sucking, chewing, tongue protrusion	Provoked/intensified by tactile stimulation	Nonepileptic
	Progression movements	Rowing, swimming, bicycling, pedaling	Provoked/intensified by tactile stimulation, suppressed by repositioning/restraint	
	Complex purposeless movements	Sudden arousal, transient increase in random limb activity	Provoked/intensified by stimulation	

Table 3: Differential diagnosis of neonatal seizures by day of presentation (Modified from Ferreiro)

<i>Day</i>	<i>Etiology</i>	<i>Example</i>
Day 1	Traumatic brain injury	Subdural, subarachnoid
	Hypoxia-ischemia	Intraparenchymal
	Stroke	Arterial more than venous
	Infection	Bacterial or viral
	Severe inborn error of metabolism	Nonketotic hyperglycinemia
	Hypoglycemia	Hypocalcemia,
Day 2	Electrolyte imbalance	hyponatremia
	Drug withdrawal	Maternal substance abuse
Day 3	Stroke	Venous thrombosis
	Traumatic brain injury	
	Inborn error of metabolism	Glucose transporter defect
Day 3	Partial inborn error of metabolism	Organic acidemia
	Benign neonatal seizures	aminoacidopathy
	Stroke	
	Drug withdrawal	Arterial or venous
	Traumatic brain injury	Maternal substance abuse

seizures. Certain limitations in the use of antiepileptic drugs in neonates include the following:

- Electrographic seizures do not always correlate with clinical seizure phenomena
- If electrographic criteria were used in the recognition and management of seizures, complete suppression is often not possible
- Few drugs have been formally tested in the neonatal population
- Oral preparations often cannot be used in neonates
- Complicated metabolism and pharmacokinetics of drugs in neonates limits their use in this population.

Phenobarbitone

Currently, this is the most commonly used first line drug in the management of neonatal seizures.

Mechanism of Action

Phenobarbitone acts by inhibition of GABA, particularly the chloride permeable GABA_A receptors. Phenobarbitone also inhibits glutamate mediated neuroexcitation.

Pharmacokinetics and Pharmacodynamics

Phenobarbitone is absorbed from the oral route although the absorption is erratic. After a single intramuscular dose, phenobarbitone has a volume of distribution of 0.81 to 0.97L/kg, the half-life is 103.4 hours and the rate of clearance is 6.4 ml/kg/hour.¹⁵ The half life is variably longer in sick newborns, being up to 400 hours in preterms and approximately 150 hours in the asphyxiated term newborn.¹⁶ The drug is metabolized in the liver and excreted through the kidneys and higher blood levels and toxicity are to be expected in hepatic and renal dysfunction. The drug circulates predominantly in the protein bound form and may be displaced by bilirubin to result in higher free levels in hyperbilirubinemia.

Usage

Phenobarbitone is used as the first line drug in the control of seizures. It is administered intravenously at a loading dose of 20 mg/kg. The drug should be infused at a rate no faster than 1 to 2 mg/kg per minute (to avoid cardiopulmonary depression). The dose with intramuscular administration should be 10 to 15 percent higher than the intravenous dose.¹⁷ Oral administration should not be used for patients who suffer frequent seizures or who are compromised. The refractory seizures characteristic of postasphyxial neurological injury is amenable to higher loading doses of 30 mg/kg given intravenously over a 15 minute period.¹⁸ Gal and colleagues used phenobarbitone as a single anticonvulsant in 71 cases of neonatal seizures. They reported 85 percent seizure control with effective therapeutic levels between 10.1 and 46.4 mg/L, with dose related incremental responses from 20 to 30 mg/kg when administered as a loading dose.¹⁹ A study comparing phenobarbitone with phenytoin showed that 13 out of 30 babies (43%) responded to phenobarbitone in a dose sufficient to achieve a plasma concentration of free drug of 25 µg/ml. The therapeutic range is generally considered to be 20 to 40 µg/ml (88-160 µmol/l).²⁰ The use of video EEG telemetry has opened new insights into the mechanism and treatability of seizures. Boylan et al²¹ studied fourteen neonates who were treated with a loading dose of 20 to 40 mg/kg of phenobarbitone. Four responded clinically as well as electrographically. In the remaining 10 neonates, electrographic seizures increased after treatment, whereas clinical seizures reduced, a phenomenon known as 'electroclinical uncoupling'. Three of these neonates were treated with second line anticonvulsants, of whom two responded. One of these had a normal neurodevelopmental score at one year, but the outcome for the remainder of the whole group was poor.

Adverse Effects and Precautions while Using

Phenobarbitone, still the most widely used first line anticonvulsant in the neonatal period, has long been known

to have long-term effects on brain growth. Newer studies have added to these concerns, with the demonstration of increased apoptotic neurodegeneration in the developing rat brain after exposure to phenobarbitone, phenytoin, and benzodiazepines.²² Apnea and hypotension may occur, especially with concomitant use of benzodiazepines.

The latent period between asphyxial injury and onset of seizure activity may provide a "therapeutic window" for prophylactic intervention. The seizures that follow hypoxic-ischemic brain injury occur 6 to 12 hours later in about half of the cases. In many instances, they are refractory to treatment and require higher doses of phenobarbital or additional anticonvulsants. It is possible that treatment during the latent period might be more effective and prevent or control seizure activity with less doses of the drug. Barbiturates administered in high doses reduce cerebral metabolic rate and cerebral edema and remove harmful free radicals.²³ Phenobarbitone was found to have adverse hemodynamic effects, limiting its use initially. However, the study by Hall et al using phenobarbitone in the dose of 40 mg/kg in severe birth asphyxia reported an improvement in long-term neurological outcome in 31 severely asphyxiated infants, is encouraging and practice guidelines to this effect are awaited.²⁴

Phenytoin

Phenytoin is used as an adjuvant to phenobarbitone therapy.

Pharmacology of Drugs

Phenytoin possesses antiseizure properties without causing significant sedation or depression of the central nervous system. In toxic doses, it may produce excitatory signs and at lethal levels, a type of decerebrate rigidity.²⁵

Mechanism of Action

Phenytoin acts by blocking voltage dependant sodium channels. By slowing the rate of recovery of these channels from inactivation, it limits repetitive firing of action potentials evoked by a sustained depolarization. Being highly lipid soluble, it enters the brain rapidly. The drug is poorly water soluble and has a high pH, a characteristic that precludes intramuscular administration. It is highly protein bound, and small variations of the proportion of free drug dramatically affect its actions. Protein binding is lower in neonates and is related to serum albumin, protein, and bilirubin concentrations.²⁵ Excretion of phenytoin is predominantly renal, the drug exhibiting first-order kinetics, and clearance is related inversely to the serum level. The elimination rate of the drug is concentration-dependent, and the half-life decreases after the first postnatal week. The half-life in neonates varies from 40 to 200 hours with a mean of 100 hours. Achievement of therapeutic levels

requires a loading dose. The drug precipitates in dextrose and this should not be used as a vehicle.

Painter et al²⁰ compared the relative efficacies of phenobarbitone and phenytoin and found that of 29 neonates given phenytoin at a dose of 15 mg/kg as first-line treatment, 13 (45%) responded. Fifteen babies, who failed to respond to phenobarbitone as a first line treatment, were given phenytoin; only four of these babies responded. Overall, the success of a combination of both drugs in controlling seizures was 60 percent. Similarly, Laroia reported that 30 percent of neonates who had received full loading doses of phenobarbitone and phenytoin continued to have seizures, suggesting that the severity of the seizures was a better predictor of the success of treatment than was the assigned agent.²⁶ Neonates with mild seizures or with a low seizures burden are more likely to have their seizures controlled regardless of the treatment assignment.

Perhaps the best known side effect of phenytoin is its propensity to cause cardiac arrhythmias and hypotension. Phenytoin should probably be avoided in neonates requiring inotropic support. The drug should be administered slowly, under cardiac monitoring at a rate not exceeding 1 mg/kg/minute. Long-term effects of phenytoin usage in neonates have not been systematically studied. Cerebellar growth and development occurs principally postnatally and the effects of phenytoin on the cerebellum raise concerns regarding its prolonged use. Ohmori et al reported pyknotic cells in the external granular layer (EGL), reduced size and weight of the cerebellum and poorly developed walking reflex and negative geotaxis on postnatal day 14 in mice following prolonged, early, exposure to phenytoin.²⁷

Valproate competes with phenytoin for binding sites on plasma proteins, leading to a marked increase in levels of free phenytoin when a combination is used. Concurrent administration of any drug which is metabolized by the cytochrome P450 pathway can increase plasma concentration by decreasing its rate of metabolism. Carbamazepine, which may enhance the metabolism of phenytoin, causes a well documented decrease in phenytoin concentrations. Interaction between phenytoin and phenobarbitone is variable.

Sodium Valproate

Sodium valproate is a simple branched chain carboxylic acid derivative. Valproate acts in a fashion similar to carbamazepine and phenytoin and appears to be mediated by a prolonged recovery of voltage activated sodium channels from inactivation. Valproate also influences GABA synthesis and breakdown, leading to an increase in GABA concentrations in the brain. There is also evidence that Valproate interferes with glutamate-mediated excitation and limits sustained repetitive neuronal firing through voltage- and use-dependent blockade of sodium channels. It is rapidly absorbed after oral administration with a

volume of distribution of 0.2 L/kg. Approximately 90 percent of the drug is protein bound and metabolism is predominantly through hepatic glucuronidation. In adults, the half-life is approximately 15 hours.²⁵ Valproate has been used in the neonatal period in cases of refractoriness to traditional anticonvulsants. Gal and colleagues²⁸ used it in six neonates who had ongoing seizures despite full doses of phenobarbitone, five of whom had been given at least two other anticonvulsants. Seizures were controlled in 5/6 (83%), and in four cases, other anticonvulsants were withdrawn and seizures were controlled with valproate monotherapy.

The plasma concentration required for therapeutic effect is 30 to 100 µg/ml. Dosages used in children typically start at 15 mg/kg/day and stepped up in increments of 5 to 10 mg/kg/day to 60 mg/kg/day.

Dosages in neonates have not been established. Following a loading dose of 10 mg/kg, one neonate studied by Alfonso et al had a 45 minutes serum level of 41 µg/ml and a three hour level of 33 µg/ml. In another neonate a dose of 25 mg/kg increased the 45 minutes level to 100 µg/ml and the 3 hours level to 78 µg/ml. Each 1 mg/kg dose increased the 45 minutes level and the subsequent 3-hour level by 4 µg/ml and 3 µg/ml, respectively. Hypotension occurred in an older child at an infusion rate of 30 mg/kg per hour (0.5 mg/kg per minute).²⁹ The maintenance dose of valproate is started at 20 mg/kg/day.

Valproate primarily inhibits drugs metabolized by CYP2C9 including phenytoin and phenobarbitone and those metabolized by UGT, thus inhibiting metabolism of lamotrigine and lorazepam. The drug occupies binding sites on albumin and displaces drugs and other metabolites from it. Hyperammonemia has been reported following the use of valproate in newborns.²⁸ Its long-term use has been found to be associated with apoptotic neurodegeneration in the developing brain.

Carbamazepine

Carbamazepine is structurally related to the tricyclic antidepressants. It is highly lipophilic and no intravenous preparation exists. The pharmacokinetic properties of carbamazepine are influenced by its limited aqueous solubility. Absorption following an oral dose is slow and erratic, with peak plasma concentrations being achieved after 4 to 8 hours. It is bound to plasma proteins to the extent of 75 percent and only free drug crosses over to the CSF. It is metabolized to the 10,11 epoxide, a compound as active as the parent drug. This is then further metabolized to inactive glucuronide products, which are excreted in the urine. The half-life is 7 to 15 hours.³⁰ Carbamazepine inhibits repetitive firing of action potentials by causing slowing of voltage activated sodium channels.

The use of carbamazepine in neonatal seizures is mainly anecdotal. Hoppen et al investigated the use of carbamazepine in ten preterm neonates weighing 630 to

3080 gram (gestation 23-34 weeks) in oral daily doses of 7 to 23 mg/kg/day in 2 to 3 divided doses. Seizures were controlled in nine out of 10 patients.³¹ Rapid loading using the oral preparation has been achieved in critically ill infants.

Phenobarbitone, phenytoin and valproate may increase the metabolism of carbamazepine by hepatic enzyme induction, while erythromycin may inhibit its metabolism.

Acute intoxication may lead to hyperirritability, seizures and respiratory depression. Long-term therapy may be associated with bone marrow depression.

Benzodiazepines

The benzodiazepines are a group of drugs which include diazepam, lorazepam, midazolam and clonazepam. They are generally used when seizures are refractory to first line anticonvulsants and act by increasing GABA-mediated inhibition through activation of the GABA_A receptor.

Although diazepam has a rapid onset of action, there also is very rapid brain clearance, and seizures are likely to recur. This property also makes maintenance therapy difficult. Diazepam has a half-life of 31 to 54 hours. Onset of action of lorazepam is 2 to 3 minutes after a loading dose and lasts for up to 24 hours. Pharmacokinetic studies by McDermott³² revealed a decreased volume of distribution and clearance, and a prolonged half-life in comparison with data from older children and adults. Lorazepam has the following advantages over diazepam: a less rapid redistribution (with longer anticonvulsant activity) and less sedation and respiratory depression.

Maytal and colleagues³³ administered IV lorazepam at 0.05 mg/kg in seven patients unresponsive to phenobarbitone and repeated it up to a total dose of 0.15 mg/kg. Lorazepam controlled seizures completely in six patients and decreased them in one child. Two patients needed only one dose, three patients received two doses, and two patients received three doses.

Midazolam, a short-acting benzodiazepine, is used to treat status epilepticus in older patients. It is associated with less sedation and respiratory depression than diazepam and lorazepam. Sheth and associates³⁴ studied its use in six neonates, in whom seizures persisted for more than 12 hours despite high-dose phenobarbitone therapy, at an initial infusion of 0.1 to 0.4 mg/kg per hour for 1 to 3 days. Clinical seizures were controlled within 1 hour in all six infants, and EEG seizures were controlled in four. Deshmukh³⁵ reported cessation of seizures in seven infants to whom they administered lorazepam at 0.05 mg/kg over 2 to 5 minutes. They noted no adverse events.

Overall, benzodiazepines are safe for newborns. In one study, 10/63 (16%) newborns had 14 documented adverse events: seizures in six, hypotension in five, and respiratory depression in three.³⁶ Sedation and hypotonia have been reported with lorazepam use, probably aggravated in the

preterm infant due to limited excretion through the normal pathway of glucuronidation. Stereotypic movements may occur, especially myoclonus, perhaps related to benzyl alcohol.

Hypotension, apnea, and lethargy may occur and are potentiated by the concomitant use of phenobarbitone. There may be prolonged effects from diazepam because of the long half-life of its metabolite, N-desmethyldiazepam, especially in the preterm infant, so it may not be appropriate for sedation or even seizure therapy. It also is possible that sodium benzoate, contained in the IV preparation, may displace bilirubin from albumin.

Topiramate

Topiramate is a sulfamate substituted monosaccharide, used principally for partial seizures in older children and adults. It reduces voltage gated sodium currents in a manner similar to phenytoin, enhances postsynaptic GABA_A receptor currents and limits activation of the AMPA-kainate subtype of glutamate receptors.³⁷ Topiramate is rapidly absorbed from the gut and excreted predominantly unchanged. The half-life is approximately 24 hours.

There are no published reports of the clinical use of topiramate in neonatal seizures. However, it holds potential as a neuroprotective agent in hypoxic ischemic encephalopathy due to its action on the glutamate AMPA-kainate receptors, activation of which is thought to result in neuronal injury.

Lignocaine

Lignocaine has been used in refractory seizures. A 2 mg/kg loading dose, followed by infusion of 6 mg/kg per hour, produced an immediate effect in 18 infants, with control achieved within 30 minutes in another five. Ultimate control was obtained in 92 percent. No serious adverse events were seen.³⁸ Drug accumulation tends to be a problem with lignocaine. Rey and colleagues³⁹ administered lignocaine to 13 neonates, using decremental doses from 4 mg/kg/d to 1 mg/kg/d over four days. Seizures were controlled in 11 of the infants, with effective plasma concentrations between 3 and 6 mg/L. Clearance is decreased in the preterm infant.

Other Drugs

There are only anecdotal reports of the use of newer anticonvulsants like lamotrigine, vigabatrin, zonisamide and levetiracetam. Lamotrigine⁴⁰ was used in the dose of 4.4 mg/kg/day in one neonate who had refractory seizures that were not controlled with several anticonvulsants. Vigabatrin⁴¹ and zonisamide⁴² have been used for refractory seizures due to the Ohtahara and Aicardi syndromes, both associated with neonatal-onset seizures. The dose for vigabatrin initially was 50 mg/kg and increased up to 200

mg/kg. The zonisamide starting dose was 2.5 mg/kg and increased to 20 mg/kg.

Pyridoxine dependency is associated with refractory seizures, 1 to 4 Hz sharp and slow wave activity and responsiveness to 50 to 100 mg of intravenous pyridoxine.⁴³ The seizures may have a prenatal onset and other associated features include hypotonia, jitteriness, irritability, and exaggerated startle reflex.

The glucose transporter deficiency (De Vivo syndrome), should be considered when CSF glucose concentrations are low and other causes of hypoglycorrhachia have been excluded, such as systemic hypoglycemia or bacterial or fungal meningitis. If not treated, microcephaly and mental retardation occur. The condition is amenable to a ketogenic diet.

DURATION OF ANTICONVULSANTS

The duration of therapy depends on the etiology and the neurological status of the infant. Transient metabolic derangements causing seizures, which have been identified and corrected, do not require anticonvulsants beyond 3 to 4 days. Phenytoin is discontinued once intravenous therapy is stopped as it is difficult to maintain reliable levels orally. Phenobarbitone is stopped if the neonate has become neurologically normal prior to discharge. If the neurological examination is abnormal at discharge, the infant is closely followed up and the phenobarbitone continued. On follow-up, the neurological examination and EEG guide therapy. If the neurological examination and EEG are normal, anticonvulsants may be stopped.

PROGNOSIS

The long-term prognosis after neonatal seizures is directly related to the cause. Newborns with seizures related to

subarachnoid hemorrhage, transient metabolic disturbance like hypocalcemia and those with a normal background EEG generally do well, whereas those with a grade III or IV intraventricular hemorrhage have a high morbidity. Early onset of seizures is associated with the highest morbidity and mortality. The longer the seizure activity continues, the more likely the neonate is to have later neurological impairment. Table 4 outlines some poor prognostic features of neonatal seizures.

Respiratory Distress in Newborns

AK Dutta

Respiratory distress in newborn accounts for significant morbidity and mortality. It occurs in 5 to 12 percent of neonates. It may denote a significant life-threatening emergency. A working diagnosis should be made within few minutes of seeing the baby and treatment initiated. Then a detailed plan of history and management can be made and carried out.

At the time of birth, the fluid in the fetal lung is rapidly replaced by air. Associated with the lung inflation and increased oxygenation there is marked reduction in the pulmonary vascular resistance, with consequent increased pulmonary blood flow and closure of ductus arteriosus, foramen ovale and ductus venosus. As a result, the lungs take over the respiratory function previously carried out by the placenta. Many pathological processes can interfere with this normal sequence of events and give rise to respiratory distress in the newborn period.

DEFINITION

Respiratory distress is characterized by the following signs:

- *Tachypnea*: A respiratory rate great than 60/ minute.
- *Expiratory Grunt*: A physiological mechanism of preventing alveolar collapse by expiring against a partially closed glottis.
- *Chest recessions*: Which may be intercostals, subcostal, sternal, substernal or suprasternal.
- Central cyanosis.
- Working of accessory muscle of respiration especially flaring of alae nasi.

Presence of two or more signs persisting for four hours or more suggest respiratory distress.

CAUSES OF RESPIRATORY DISTRESS

It can be broadly classified into most common causes and less common but significant causes (Table 1). The causes

Table 1: Causes of respiratory distress in order of frequency

*Most common causes**

- Transient tachypnea of the newborn
- Respiratory distress syndrome (hyaline membrane disease)
- Meconium aspiration syndrome

Less common but significant causes

- Delayed transition
- Infection (e.g. pneumonia, sepsis)
- Nonpulmonary causes (e.g. anemia, congenital heart disease, congenital malformation, medications, neurologic or metabolic abnormalities, polycythemia, upper airway obstruction)
- Persistent pulmonary hypertension of the newborn
- Pneumothorax

** Listed in order of incidence*

of respiratory distress can also be broadly classified as per etiology that is non-respiratory and respiratory and in the respiratory causes as medical and surgical (Table 2). Accurate diagnosis is important for appropriate care. Rare causes should be considered when no cause is suggested by the initial history and examination.

TRANSIENT TACHYPNEA OF NEWBORN

Transient tachypnea of newborn (TTNB) is the most common cause of neonatal respiratory distress. A benign condition, it occurs when residual pulmonary fluid remains in the fetal lung tissue after delivery. Risk factors include male sex, macrosomia, maternal diabetes and cesarean delivery. The clinical presentation includes signs of respiratory distress immediately after birth or within two hours after birth. Symptoms can last for few hours to two days. Chest radiograph shows diffuse parenchymal infiltrates, a "wet silhouette" around the heart or interlobar fluid accumulation (Fig. 1).

Congenital pneumonia	
Meconium aspiration syndrome	
<i>Air leaks:</i> Pneumothorax and pulmonary interstitial pneumonia	
Pulmonary hypoplasia	
Pulmonary hemorrhage	
<i>Surgical:</i>	
Choanal atresia, Pierre Robin sequence, diaphragmatic hernia, esophageal atresia with tracheoesophageal fistula, congenital lobar emphysema, cystic adenomatoid malformation	

RESPIRATORY DISTRESS SYNDROME

Respiratory distress syndrome (RDS) is the most common cause of respiratory distress in the premature infants correlating with the structural and functional lung immaturity. It is most common in infants born before 28 weeks gestation. Prevalence without antenatal steroids at <28 weeks GA is 60 percent, 28 to 31 weeks GA is 40 percent, 30 to 34 weeks is 15 percent and ≥34 weeks GA is 5 percent. Antenatal steroid therapy reduces this prevalence by 50 percent. The condition is more common in male infants. Incidence is approximately six times higher in infants of diabetic mothers.

The diagnosis of respiratory distress should be suspected when grunting, tachypnea and retractions occur in a premature infant immediately after birth. Chest radiograph shows homogeneous infiltrates and air bronchograms, indicating contrast in airless lung tissue seen against air-filled bronchi (Fig. 2).

MECONIUM ASPIRATION SYNDROME

Meconium-stained amniotic fluid occurs in approximately 15 percent of the deliveries. Ten to fifteen percent of these babies have meconium aspiration syndrome (MAS). MAS

Fig. 1: Chest radiograph of newborn with transient tachypnea of newborn

Fig. 2: Chest radiograph of newborn with respiratory distress syndrome

Fig. 3: Chest radiograph of newborn with meconium aspiration syndrome

causes significant respiratory distress because meconium is locally irritative, obstructive and a medium for bacterial growth. Chest radiographs show patchy atelectasis or consolidation (Fig. 3). There may be air leaks.

CONGENITAL PNEUMONIA

Risk factors for pneumonia include prolonged rupture of membrane, prematurity and maternal fever. Common pathogens include GBS, *Staphylococcus aureus*, *Streptococcus pneumoniae*, and gram-negative enteric bacilli. Unlike TTNB and RDS, bacterial infection takes time to develop, with respiratory consequences occurring hours to days after birth. Chest radiograph shows bilateral infiltrates. (Fig. 4). Pleural effusion may be present.

PERSISTENT PULMONARY HYPERTENSION OF NEWBORN

It is a condition characterized by marked pulmonary hypertension resulting from elevated pulmonary vascular resistance and altered pulmonary vasoreactivity, leading to right to left extrapulmonary shunting of blood across the foramen ovale and PDA. Persistent pulmonary hypertension of newborn (PPHN) may result from underdevelopment of lung together with vascular bed (CDH, hypoplastic lungs) and maladaptation of the pulmonary vascular bed to the transition occurring at the time of birth (perinatal stress, hemorrhage, aspiration, hypoxia, and hypoglycemia). The primary finding is respiratory distress with cyanosis. This may occur despite adequate ventilation. In an infant with pulmonary disease PPHN should be suspected when there is marked lability in oxygenation. Cardiac signs may include a prominent right ventricular impulse, a single second heart sound, and a murmur of tricuspid insufficiency.

Fig. 4: Chest radiograph of newborn with congenital pneumonia

The chest X-ray may show normal sized heart or cardiomegaly. If there is no associated pulmonary pathology, vascularity may be normal or decreased. Echocardiography is essential in distinguishing PPHN from congenital heart disease. It may show flattened or septum bowed to the left suggestive of pulmonary hypertension. Color Doppler may reveal evidence of tricuspid regurgitation.

PNEUMOTHORAX

It is defined as air in the pleural space, can be cause of neonatal respiratory distress. It can occur spontaneously or as a result of infection, meconium aspiration, lung malformation or ventilator barotraumas. The incidence of spontaneous is one to two percent in term and 6 percent in preterm babies. Presence of cyanosis, sudden increase in tachypnea, bradycardia and shock may suggest that there is tension pneumothorax. There may be asymmetric chest with a bulge on the affected side, decreased breath sounds on the affected side and shift of the cardiac apical impulse away from the affected side. In an emergency transillumination can help in making a decision about doing an urgent needle decompression. Chest radiograph is diagnostic. It may show displacement of the lung on the affected side away from the chest wall by a radiolucent band of air, a shift of mediastinum away from the affected side and depression of the diaphragm on the affected side (Fig. 5).

CONGENITAL DIAPHRAGMATIC HERNIA

Herniation of abdominal visceral contents through the posterolateral foramen of Bochdalek or the anterior foramen of Morgagni leads to Congenital diaphragmatic hernia (CDH). Presence of abdominal viscera in the chest during the fetal life prevents normal development of the

Fig. 5: Chest radiograph of newborn with right pneumothorax

Fig. 6: Chest radiograph of newborn with congenital diaphragmatic hernia

lungs. A history of polyhydramnios is commonly present. Postnatally cyanosis, retraction tachypnea and grunting are commonly seen. On examination abdomen is scaphoid, the anteroposterior diameter of the chest is increased, mediastinum is shifted, and bowel sounds may be heard in the chest. Presentation may be delayed in the less severely affected babies. The diagnosis is made on chest radiograph which shows air filled bowel loops in the chest cavity with nonvisualization of diaphragmatic margin, mediastinal shift and relative paucity of abdominal gas (Fig. 6).

Congenital Cystic Adenomatoid Malformation

Congenital cystic adenomatoid malformation (CCAM) is characterized by a mass of cysts that may or may not intercommunicate. The primary defect is segmental bronchial atresia. Cysts may vary in size from few large cysts to a large number of microcysts. Symptoms of respiratory distress may develop soon after birth. Recurrent respiratory infection is common mode of presentation. Plain chest X-ray may show multiple air filled spaces (macrocyts) or a solid area within the lung (microcysts) (Fig. 7). CT of the chest is diagnostic (Fig. 8).

Fig. 7: Chest radiograph of newborn with CCAM

CONGENITAL LOBAR EMPHYSEMA

It is defined as postnatal over distention of one or more segments or lobes of the lungs. This over distended portion of the lung compresses the adjacent lung and compromises ventilation. Left upper lobe is involved most commonly. Males are affected three times as compared to females. The presentation is with respiratory distress. Physical examination reveals hyperresonance with decreased air entry on the affected side. Chest X-ray shows hyperlucent hyperexpanded area of the lung with compression or atelectasis

of the adjacent lobes of the lungs, depression of the diaphragm and mediastinal shift to the opposite side.

ESOPHAGEAL ATRESIA WITH OR WITHOUT TRACHEOESOPHAGEAL FISTULA

It is the most common surgical condition leading to respiratory distress. Neonates present soon after birth with frothing at the mouth or choking with attempted feeds or with manifestations of aspiration pneumonitis. An obstruction to the

Fig. 8: CT chest of newborn with CCAM

passage of an orogastric tube at about 10 cm from mouth is usually diagnostic and dye studies are not required for confirmation. A chest X-ray showing coiling of an orogastric tube in upper pouch is fairly diagnostic (Figs 9A to C).

CHOANAL ATRESIA

It is a congenital blockage of the posterior nares caused by persistence of bony septum (90%) or a soft tissue membrane (10%). Choanal atresia which is bilateral and complete causes respiratory distress immediately after birth because neonates are obligate nose breathers. Diagnosis is suspected by inability to pass a catheter into the nasopharynx via either side of nose. CT nasopharynx is diagnostic (Fig. 10).

EVALUATION OF RESPIRATORY DISTRESS

History

A detailed history is critical to proper evaluation. The differential diagnosis changes with gestational age: respiratory distress syndrome typically affects preterm infants, whereas meconium aspiration syndrome affects term and post-term neonates. Antepartum infection status is important. Information about duration of rupture of membranes, color of amniotic fluid, maternal temperature, maternal tachycardia and fetal heart tracings status is vital to detect meconium aspiration and chorioamnionitis. Family history assists in identifying inheritable congenital defects. The onset and duration of respiratory symptoms also provides clues. Transient tachypnea of newborns begins early and improves with time. Conversely sepsis and pneumonia may have no early signs but may develop hours to days later. Respiratory distress syndrome begins early in premature infants without signs of spontaneous improvement.

Figs 9A to C: Chest radiograph of newborn showing esophageal atresia

Fig. 10: CT nasopharynx of a newborn showing right sided choanal atresia

Examination

The severity of distress should be estimated with initial assessment. Mild distress may warrant observation and pulse oximetry. Severe distress, especially with a complicated birth history, requires immediate resuscitation, chest radiography and lab tests (Flow chart 1).

Severity of Respiratory Distress

Silverman-Anderson and Downes' scores (Tables 3 and 4) are used to grade the severity of respiratory distress. While the Silverman-Anderson score is more suited for preterm with respiratory distress, the Downes' score is more comprehensive and can be applied to any gestational age and condition. Scoring should be at hourly intervals and chart maintained to determine progress. A progressively increasing FiO_2 requirement to maintain saturation of 90

Flow chart 1: Management of respiratory distress

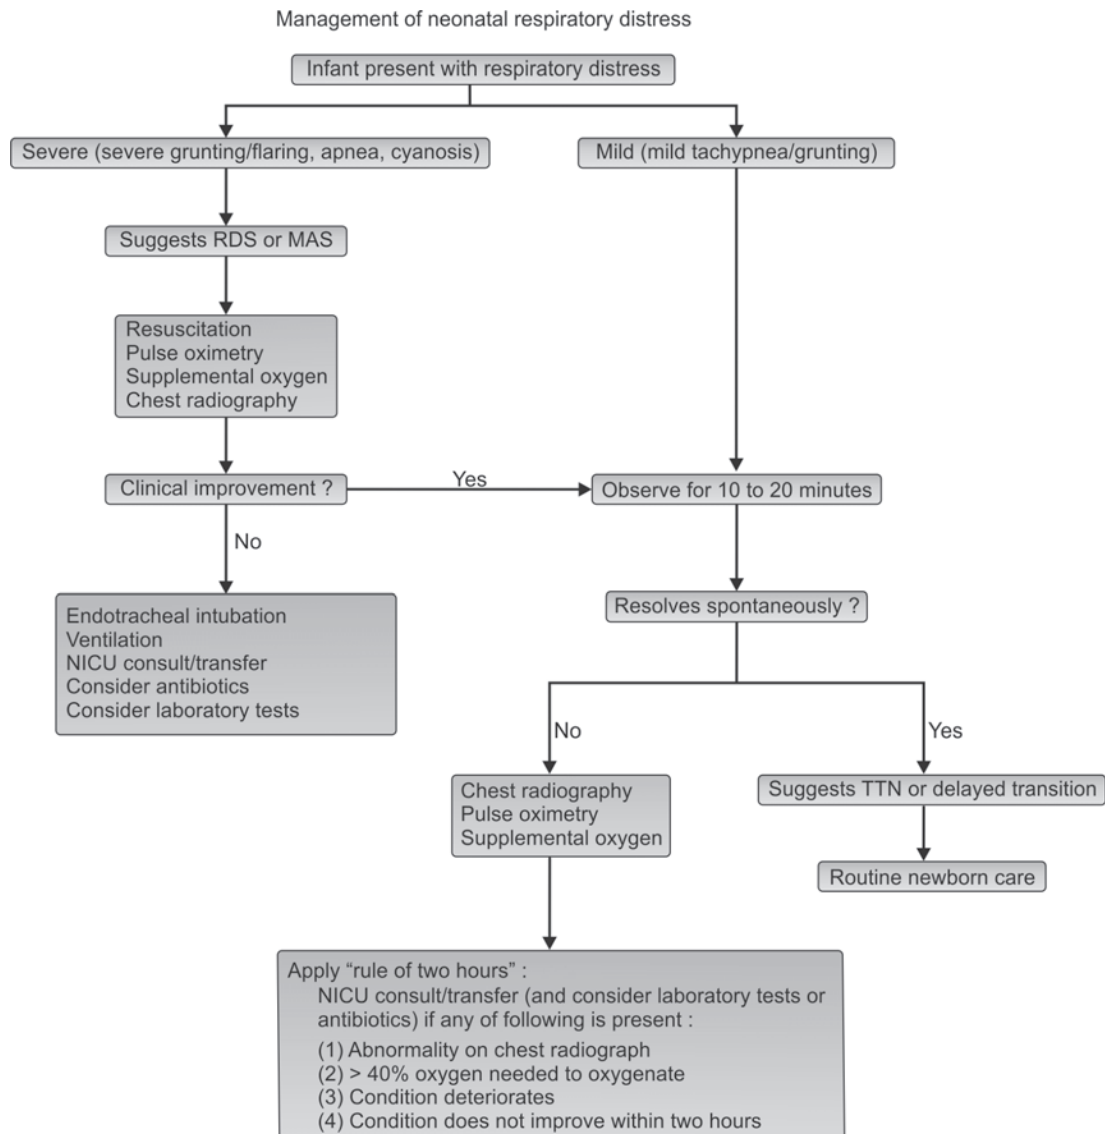

Table 3: Silverman Anderson retraction score

Score	Upper chest retraction	Lower chest retraction	Xiphoid retraction	Nasal dilatation	Grunt
0	Synch	None	None	None	None
1	Lag on inspiration	Just visible	Just visible	Minimal	Stethoscope only
2	See-saw	Marked	Marked	Marked	Naked ear

A score of >6 is indicative of impending respiratory failure

Table 4: Downes' score

Score	Respiratory rate	Cyanosis	Air entry	Grunt	Retraction
0	<60/min	Nil	Normal	None	Nil
1	60-80/min	In room air	Mild ?	Ausc with stethoscope	Mild
2	>80/min	In $\geq 40\%$	Marked ?	Audible with naked ear	Moderate

A score of >6 is indicative of impending respiratory failure

to 92 percent in preterm and 94 to 96 percent in a term baby is also a sensitive indicator of the severity and progress of distress.

Clues to likely diagnosis can be picked up on examination of the neonate. A preterm baby weighing <1500 grams with retractions and grunt is likely to have RDS. A term or post-term baby born through meconium stained amniotic fluid with increase in the anteroposterior diameter of the chest is likely to have MAS. A near term baby with no risk factors and mild distress most probably has TTNB. A growth retarded baby who looks plethoric might be having respiratory distress due to polycythemia.

An obstruction to the passage of an orogastric tube at about 10 cm from mouth is suggestive of esophageal atresia and TEF. Inability to pass 5F catheter through the nostril of a term baby is suggestive of choanal atresia. A baby with respiratory distress should be checked by placing a cold light over the chest light source over the chest wall in a darkened room. Transillumination is suggestive of air leak.

Investigations

Essential investigations for all cases of respiratory distress include chest radiograph, arterial blood gas, sepsis screen, blood culture, and blood glucose and serum calcium (Table 5).

The distinguishing features of TTNB, RDS and MAS three of the most common causes of respiratory distress presenting in a NICU have been summarized in the Table 6.

TREATMENT

General Supportive Treatment

Clearing of airway, ensuring adequate breathing and circulation are the first line of management. A baby in obvious respiratory distress needs to be on continuous pulse oximeter monitoring to decide when intubation and ventilation is

Table 5: Lab evaluation for respiratory distress

Test	Indication
Blood culture	May indicate bacteremia Not helpful initially because results may take 48 hours
Blood gas	Used to assess degree of hypoxemia if arterial sampling, or acid/base status if capillary sampling (capillary sample usually used unless high oxygen requirement)
Blood glucose	Hypoglycemia can cause or aggravate tachypnea
Chest radiography	Used to differentiate various types of respiratory distress
Complete blood count with differential diagnosis	Leukocytosis or bandemia indicates stress or infection Neutropenia correlates with bacterial infection Low hemoglobin level shows anemia High hemoglobin level occurs in polycythemia Low platelet level occurs in sepsis
Lumbar puncture	If meningitis is suspected
Pulse oximetry	Used to detect hypoxia and need for oxygen supplementation

required. Warm humidified oxygen is given with a head box preferably with a FiO₂ meter and pulse oximeter monitoring to determine the amount of oxygen required. Soft nasal cannula may also be used to give oxygen. Maintenance of correct temperature is essential. RDS and PPHN get

Table 6: Distinguishing features of TTNB, RDS and MAS

<i>Cause</i>	<i>Etiology</i>	<i>Timing of delivery</i>	<i>Risk factors</i>	<i>Clinical features</i>	<i>Chest radiography findings</i>
TTN	Persistent lung fluid	Any	Cesarean delivery Macrosomia Male sex Maternal asthma Maternal diabetes	Tachypnea Often no hypoxia or cyanosis	Parenchymal infiltrates “Wet silhouette” around the heart Intralobar fluid accumulation
RDS	Surfactant deficiency	Preterm	Male sex Maternal diabetes Preterm delivery	Tachypnea Hypoxia Cyanosis	Homogenous infiltrates Air bronchograms Decreased lung volumes
MAS	Lung irritation and obstruction	Term or post-term	Meconium stained amniotic fluid Post-term delivery	Tachypnea Hypoxia	Patchy atelectasis Consolidation

worsened if the baby is hypothermic. Electrolyte balance, fluid, calcium and glucose homeostasis are equally important. Fluids are usually started at a minimum of 60 ml/kg/day of 10 percent Dextrose. A minimum glucose infusion rate of 4 mg/kg/min should be ensured. Calcium in the dose of 6 to 8 ml/kg/day of calcium gluconate should be added to the fluid in all babies with respiratory distress. Packed cell volume should be maintained above 40 percent. All preterm babies with respiratory distress may be started on broad-spectrum antibiotics. In term babies, decision to start antibiotics would depend upon the clinical situation.

Respiratory Support

It is given in the form of continuous positive airway pressure (CPAP) or intermittent mandatory ventilation (IMV). CPAP should be started early in preterm with RDS. Indication for starting CPAP are Downe's score of >6 at birth or FiO_2 requirement of >0.4 to maintain an acceptable saturation on pulse oximeter. For best outcomes SIMV should be given to babies in impending respiratory failure or failed CPAP rather than in complete respiratory failure. CPAP is said to have failed when the FiO_2 requirement is >0.6 or the pressure required to maintain oxygenation exceeds 7 to 8 cm of H_2O . Respiratory failure is defined as $\text{PCO}_2 > 60$ mm or $\text{PO}_2 < 50$ mm or saturation <85 percent in 100 percent O_2 with or without a pH <7.25.

Specific Treatment

Pneumothorax

Tension pneumothorax must be drained immediately. A 21- or 23-gauge needle or 22- or 24-gauge angiocath is attached to a 20 ml syringe. The needle is inserted above the third rib at midclavicular line and advanced until air is withdrawn from the syringe. It may be left in place for continuous drainage till the time a chest tube is placed.

Respiratory Distress Syndrome

Babies with or at high risk of RDS should be given a natural surfactant preparation. Prophylaxis (within 15

minutes) should be given to almost all babies of <26 weeks gestation. Prophylaxis should also be given to all preterm babies with RDS who require intubation for stabilization. Early rescue surfactant should be administered to previously untreated babies if there is evidence of RDS. Immediate extubation to CPAP or NIPPV should be considered following surfactant provided baby is stable.

Surgery

It is required for TEF, CDH, choanal atresia, congenital lobar emphysema and CCAM.

PREVENTION

Antenatal Steroids

Cochrane review which included 21 studies came to the conclusion that treatment with antenatal steroids does not increase risk to mother of death, chorioamnionitis or puerperal sepsis. Treatment with antenatal corticosteroids is associated with overall reduction in neonatal death (RR 0.69 95% CI 0.58-0.81), RDS (RR 0.66, 95% CI 0.59 to 0.73), cerebroventricular hemorrhage (RR 0.54, 95% CI 0.43 to 0.69), necrotizing enterocolitis (RR 0.46, 95% CI 0.29 to 0.74), respiratory support, intensive care admissions (RR 0.80, 95% CI 0.65 to 0.99) and systemic infections in the first 48 hours of life (RR 0.56, 95% CI 0.38 to 0.85).

Any woman in preterm labor 24-34 weeks of gestation irrespective of PROM, hypertension, diabetes should receive injection betamethasone 12 mg intramuscular every 24 hr × 2 doses or injection dexamethasone 6 mg IM every 12 hr × 4 doses.

GBS Prophylaxis

Guidelines were published by CDC in 2002 which have lately been revised in 2010. Pregnant women should undergo vaginal-rectal screening for GBS colonization at 35-37 weeks. Intrapartum antibiotic prophylaxis is recommended for women who have previously delivered an infant with GBS disease, women with GBS bacteriuria in the current

pregnancy, women with positive GBS screening result in current pregnancy, and women with unknown GBS status who deliver at less than 37 weeks gestation, have an intra partum temperature of 100.4°F or greater, or have a rupture of membrane for 18 hr or longer. Penicillin remains the preferred agent with ampicillin as an acceptable alternative.

CONCLUSION

Respiratory distress is common immediately after birth, typically caused by abnormal respiratory function during transition from fetal to neonatal life. It is manifested by tachypnea, nasal flaring, intercostals or subcostal retractions, audible grunting and cyanosis. It should also be kept in mind that not all respiratory distress may be due to pulmonary pathology. A low threshold for hospital admission is necessary. Neonatal respiratory distress may be transient; however persistent distress requires a rational diagnostic and therapeutic approach to optimize outcome and minimize mortality.

CHAPTER 12

Respiratory Distress Syndrome

Naveen Gupta

Abstract

Respiratory distress syndrome (RDS) is seen primarily in the preterm neonate and is due to mostly pulmonary surfactant deficiency. Lung atelectasis leads to ventilation-perfusion mismatching, hypoxia, and eventual respiratory failure in the untreated infant who has RDS. RDS is diagnosed by physical findings consistent with respiratory distress and characteristic radiographic findings. Treatment of RDS begins antenatally with the administration of maternal steroids to women at risk of preterm delivery between 24 and 34 weeks' gestation. The use of repeat doses of antenatal steroids is under investigation but is currently not recommended outside of randomized, controlled trials. Surfactant has been approved for use since 1990 and has been successful in decreasing rates of RDS. Natural surfactant is currently recommended for use, but synthetic surfactant that contains proteins to mimic surfactant proteins is being investigated. In general, prophylactic use of surfactant is recommended over rescue treatment in infants at high risk for developing RDS, but the determination of which infants are at high risk for developing RDS remains a clinical one. The push toward use of less invasive ventilation strategies in the treatment of RDS has led to several trials of nasal continuous positive airway pressure (nCPAP). Several complications of the recommended treatments for RDS have been identified, but the benefits far outweigh the risks. Finally, there remains a need for long-term follow-up studies on preterm neonates treated for RDS to assess neurodevelopmental outcomes.

DEFINITION

Respiratory distress syndrome formerly known as hyaline membrane disease, occurs in incompletely developed lungs and is, therefore, a disease of prematurity. Immature

lungs are functionally deficient in mature surfactant. The absence of surfactant in the liquid film lining of alveoli causes an increase in surface tension and alveolar collapse. If not treated, such atelectasis causes an increased work of breathing, intrapulmonary shunting, ventilation-perfusion mismatch, hypoxia, and eventual respiratory failure.

EPIDEMIOLOGY

Respiratory distress syndrome is seen almost exclusively in preterm infants, before the lungs begin to manufacture adequate amounts of surfactant. In fact, the risk of RDS decreases with increasing gestational age: 60 percent of babies born at fewer than 28 weeks' gestation, 30 percent of babies born between 28 and 34 weeks' gestation, and fewer than 5 percent of babies born after 34 weeks' gestation develop RDS. Other factors that increase the risk of RDS include male sex, maternal gestational diabetes, perinatal asphyxia, hypothermia, and multiple gestations. Antenatal steroids and prolonged rupture of membranes decrease the risk of RDS. With the advent of therapies for

Table 1: Normal lung development

<i>Phase</i>	<i>Embryonic</i>	<i>Pseudoglandular</i>	<i>Canalicular</i>	<i>Saccular</i>	<i>Alveolar</i>
Gestation (weeks)	0 to 7	7 to 17	17 to 27	28 to 36	36+
Structures	Trachea and bronchi	Conducting airways and terminal bronchioles	Respiratory bronchioles, alveolar ducts, primitive alveoli	Enlarged peripheral airways and thin alveolar wall	Definitive alveoli
Type II pneumocytes	Absent	Immature; undifferentiated	Immature; differentiated	Developing lamellar bodies	Mature

RDS, including antenatal steroids and SRT, mortality from RDS has decreased from nearly 100 percent to less than 10 percent in recent years.

PATHOPHYSIOLOGY

Normal Lung Development

The period of viability begins at around 23 weeks' gestation, when the fetal lung begins to transition from the canalicular to the saccular stage of development (Table 1). During the saccular stage, peripheral airways enlarge and distal airways begin to dilate while their walls begin to thin. Type II pneumocytes, the cells responsible for surfactant production, are present and maturing. Although gas exchange is possible during this stage, total surface area for gas exchange is low and diffusion distance for gas exchange is high in relation to body weight and metabolic rate. Secondary septation, or alveolarization, begins at about 32 weeks' gestation. During this phase, alveoli form and mature and alveolar walls thin. All cell types proliferate during this phase, including type II pneumocytes. The overall result is a maturing lung with a larger surface area and a minimal diffusion distance for gas exchange.

Surfactant Composition and Life Cycle

Surfactant is a mixture of phospholipids and proteins. The most abundant surface-active phospholipid in mature lungs is phosphatidylcholine. Phosphatidylcholine forms a monolayer on the liquid film lining of the alveolus, lowering the surface tension of that film. In addition to phospholipids, surfactant contains four major proteins: surfactant proteins (SPs) A, B, C, and D (Table 2). SP-A helps to regulate surfactant secretion and uptake; SP-B and SP-C facilitate adsorption and spreading of phospholipids on the liquid film lining of the alveoli. SP-D may play a role in surfactant reuptake and recycling.

Pulmonary surfactant is manufactured in the Golgi apparatus and stored in lamellar bodies of type II pneumocytes. Once secreted by the lamellar bodies into the extracellular space, surfactant is organized into tubular myelin, adsorbed into the air-water interface, and formed into a lipid monolayer. The surface-active properties of

Table 2: Surfactant proteins and their functions

<i>Surfactant proteins</i>	<i>Functions</i>
SP-A	Part of the host innate immune defense Facilitates the formation of tubular myelin Regulates surfactant secretion and uptake
SP-B	Promotes adsorption and spreading of pulmonary surfactant
SP-C	Promotes adsorption and spreading of pulmonary surfactant
SP-D	Part of the host innate immune defense May play a role in pulmonary surfactant reuptake and recycling

the lipid monolayer decrease the surface tension of the air-water interface and prevent alveolar collapse. The majority of surfactant constituents are believed to be recycled, either through reuptake by type II pneumocytes or by alveolar macrophages.

An infant born before the alveolarization stage of lung development has underdevelopment of alveolar sacs and difficulty with oxygenation and ventilation. Similarly, an infant born before this stage of lung development experiences a delay in production and secretion of functional surfactant. Such surfactant deficiency is the major reason for poor lung function in the preterm neonate.

Although the preterm neonate does produce a small amount of surfactant, this surfactant contains low amounts of phospholipids and SPs. It is estimated that infants who have RDS have surfactant pools of less than 10 mg/kg compared with pools of up to 100 mg/kg in term infants. Such surfactant deficiency necessitates increased work of breathing to distend alveoli, which the preterm neonate may not be able to provide. Diffuse atelectasis ensues and leads to an overall decrease in functional residual capacity (FRC) of the lungs. If an infant is allowed to breathe from an inadequate FRC, lung injury can occur. Lung injury leads to protein exudation and edema, which can inactivate surfactant further. The acidosis and hypoxia that results from atelectasis and lung injury further interferes

with surfactant production. The combination of these events leads to respiratory failure.

CLINICAL FEATURES

Respiratory distress syndrome presents at the time of or soon after birth, and symptoms worsen over time. Clinical symptoms of RDS are the same as those of any other respiratory distress: tachypnea, nasal flaring, chest wall retractions, expiratory grunting, and central cyanosis. In the extremely preterm infant, the only clinical symptom of RDS may be apnea. It is important to remember that some infants who have RDS exhibit all of these symptoms, and others may show none.

An accurate history is important in diagnosing RDS. As stated, RDS is more prevalent in earlier gestational ages, so an accurate estimation of gestational age is necessary. Other historical factors must be discerned, such as antenatal steroid therapy; maternal history of gestational diabetes; course of labor, including prolonged rupture of membranes, maternal fever, group B *Streptococcus* (GBS) status and antibiotic therapy; method of delivery; and need for resuscitation.

INVESTIGATIONS

Along with the history and physical examination, a chest radiograph is needed for the diagnosis of RDS. The typical chest radiograph shows diffuse atelectasis and the classic “ground-glass” appearance of the lung fields. Air bronchograms, which are air-filled bronchi superimposed on the relatively airless parenchyma of the lung tissue, also are seen commonly on chest radiograph. Importantly, the appearance of GBS pneumonia on chest radiograph can be identical to that of RDS. Empiric antibiotics to address GBS infection should be started until such disease is ruled out. Arterial blood gas measurements show hypercarbia and hypoxia and eventually, in the unsupported infant, metabolic acidosis. In all, a preterm infant must have clinical signs of respiratory distress and a classic chest radiograph to be diagnosed with RDS.

MANAGEMENT

Antenatal Steroids

Antenatal steroid administration to women at high risk of preterm delivery prior to 34 weeks’ gestation has been standard of care since the 1994 National Institutes of Health (NIH) Consensus Conference. A Cochrane review by Roberts and Dalziel from 2006 confirmed the benefits of antenatal steroids, which include decreases in neonatal death, intraventricular hemorrhage (IVH), and RDS. Antenatal steroids are believed to decrease the incidence of RDS by accelerating maturation of the fetal lung.

Early studies on the use of antenatal steroids did not include data on babies who were delivered before 28 weeks’ gestation, so there was a question of whether antenatal steroids would be beneficial in this age group. The Roberts and Dalziel review shows that when steroids are administered initially at 26 weeks’ gestation, there is a decreased incidence of RDS that is not seen if steroids are administered before 26 weeks’ gestation. However, the incidence of IVH still may be reduced if steroids are administered at fewer than 26 weeks’ gestation. Therefore, because of the apparent benefit to preterm infants in terms of decreased IVH, antenatal corticosteroid administration is recommended for preterm infants starting at 24 weeks’ gestation.

Both betamethasone and dexamethasone have been studied and found to be more effective than placebo, but these steroids have not been examined head-to-head. The Roberts and Dalziel review suggests that beta methasone may cause a larger reduction in RDS than dexamethasone. Baud and colleagues found that antenatal exposure to betamethasone, but not dexamethasone, is associated with a decreased risk of periventricular leukomalacia (PVL) in preterm infants, but there is no difference in the incidence of cerebral palsy. With this limited evidence, two doses of beta methasone administered 24 hours apart is currently the recommended steroid for antenatal use.

Antenatal steroid administration has been shown to be beneficial if provided fewer than 24 hours before delivery. Therefore, steroid administration is recommended before delivery of preterm infants 24 to 34 weeks’ gestation unless delivery is imminent. Furthermore, a reduction in RDS has been seen in infants born up to 7 days after the first dose of antenatal steroids was administered. No benefit is seen in infants who receive the first dose of steroids more than 7 days before birth.

Because antenatal steroids seem to be of benefit only when administered from just before birth to 7 days before delivery, the utility of repeated antenatal steroid dosing has been studied. The latest Cochrane review on the subject, conducted by Crowther and Harding in 2007, suggests that repeat doses of prenatal steroids do reduce the incidence and severity of neonatal lung disease in the first few postnatal weeks. They recommend repeat doses of corticosteroids in women at risk for preterm birth when the first course of steroids was administered more than 7 days previously because of the short-term benefits to the fetal lungs. They do, however, warn about the possibility of decreased birth weight and head circumference at birth, which has been reported. For example, repeat antenatal steroid courses in fetal sheep result in increased lung maturation as well as increased growth restriction. Guinn and colleagues showed that the composite neonatal morbidity, including severe RDS, bronchopulmonary dysplasia (BPD), severe IVH, PVL, sepsis, necrotizing

enterocolitis, or perinatal death, was not reduced by using weekly courses as compared with one course of antenatal steroids. Because the true risk-to-benefit ratio of using repeat doses of antenatal steroids is not known, the 1994 and 2000 NIH Consensus Conference recommends the use of repetitive courses of steroids only in the context of randomized, controlled trials.

SURFACTANT

SRT was approved for use by the United States Food and Drug Administration in 1990. Immediate improvement in oxygenation, along with improved aeration on chest radiograph within 1 hour, is seen after administration of SRT. SRT reduces the incidence of RDS, death, pneumothorax, pulmonary interstitial emphysema (PIE), and IVH in preterm infants. Although most available evidence suggests that SRT increases survival rates without increasing the risk of disability, the risk of long-term disability is unknown due to few reported follow-up studies on the preterm infants who have received surfactant.

Surfactant is administered directly into the lungs via an endotracheal tube. Other methods of surfactant administration, including aerosolization, nebulization, and instillation via bronchoalveolar lavage, have been found to be ineffective. Surfactant administration via laryngeal mask airway is being studied. Surfactant can be administered as either two or four fractional doses in either two or four different body positions; clinical evidence is not sufficient to recommend an optimal number of fractional doses. Surfactant can be administered as either a bolus or an infusion into the endotracheal tube; again, data in humans are insufficient to recommend an optimal method of surfactant administration. Interestingly, data examining the distribution of surfactant in mechanically ventilated rabbits showed that bolus instillation resulted in reasonably homogeneous pulmonary surfactant distribution, while tracheal infusion resulted in extremely uneven pulmonary distribution.

Natural and synthetic surfactant preparations exist, and both are effective in the treatment and prevention of RDS. Natural surfactants are derived from animal lungs (bovine or porcine) and contain phospholipids with SP-B and SP-C; first-generation synthetic surfactants contain only phospholipids without proteins. A Cochrane meta-analysis by Soll and Blanco conducted in 2001 comparing natural surfactant to first-generation synthetic surfactant confirmed that natural surfactant more effectively reduces the risk of pneumothorax and lowers mortality rates in infants treated for RDS. There is also a marginal decrease in the risk of BPD when using natural surfactant. Although natural surfactants appear to be associated with higher rates of IVH, grade 3 and 4 IVH rates are not increased. The conclusion of this meta-analysis is that natural

surfactants are the more desirable choice over the first-generation synthetic surfactants, which is likely due to the inclusion of the SPs in the natural surfactant.

Synthetic surfactants containing peptides that mimic SPs recently have been developed and tested. In a meta-analysis of two studies comparing protein-containing synthetic surfactant to natural surfactant, no statistically significant differences were found between the two groups in terms of death or chronic lung disease (CLD), and clinical outcomes were generally similar. Further studies comparing these two groups are needed.

The use of prophylactic versus selective administration of surfactant has been studied thoroughly. Prophylactic SRT involves intubation and surfactant administration in preterm infants at high risk for RDS and usually occurs after the initial resuscitation and within 10 to 30 minutes of birth. Prophylactic SRT has the advantage of establishing a normal surfactant pool before damage due to a low FRC, and an increased work of breathing can occur. Its major disadvantage is the possibility that an infant who would not have developed RDS may be intubated and treated with surfactant. Selective, or rescue, SRT is the administration of surfactant to preterm infants who already have developed RDS. The two types of selective SRT are early and late. Early selective SRT is administered within 1 to 2 hours of birth; late selective SRT occurs 2 or more hours after birth. The advantage of selective SRT is the avoidance of overtreatment, but in those infants who develop RDS, the delay in treatment allows lung inflammation and damage to occur.

In the Cochrane review by Soll and Morley in 2001, the use of prophylactic surfactant in infants at high risk of developing RDS was compared with selective surfactant treatment at the time of respiratory failure. Prophylactic surfactant treatment was associated with a significant reduction in the risk of pneumothorax, PIE, mortality, and BPD or death. A secondary analysis of infants of fewer than 30 weeks' gestation found a significant decrease in the risk of mortality and the risk of BPD or death. The conclusion of this study is that prophylactic surfactant is beneficial in preterm infants believed to be at high risk for developing RDS, but the best method of determining if an infant is at high risk for developing RDS remains unclear.

Because the incidence of RDS decreases with increasing gestational age, it becomes likely that prophylactic treatment with surfactant once gestational ages approach 28 to 30 weeks results in a good percentage of overtreatment. In these cases, it may make more sense to treat selectively with surfactant. The most recent Cochrane review examining early versus late selective surfactant administration found that early selective SRT decreased neonatal mortality, pneumothorax, PIE, and the incidence of CLD and death at 36 weeks' postmenstrual age when compared with late selective SRT.

Finally, in 1999, a Cochrane review compared multiple versus single doses of natural surfactant for the treatment of RDS. The reason for this comparison was the observation that some infants seemed to relapse after initial surfactant treatment. In this meta-analysis, a more sustained response in the treatment of RDS was seen in the group of infants allowed to have multiple doses of surfactant. A decreased risk of pneumothorax and a trend toward a decreased risk of mortality also was reported.

Overall, survival without BPD has increased since SRT began, although the incidence of BPD in very low-birth weight infants is unchanged. The risk of respiratory problems later in infancy or childhood (including asthma and infection) remains high for preterm infants who were treated with surfactant and mechanical ventilation. Long-term studies are needed to assess the respiratory function of children who received surfactant as preterm infants.

VENTILATORY MANAGEMENT

Several methods can be used to ventilate the preterm neonate at risk for RDS. Surfactant administration followed by conventional ventilation has historically been the management of choice, but concerns that both positive pressure ventilation via the endotracheal tube and the duration of mechanical ventilation have direct effects on the incidence of BPD have prompted investigators to search for less harsh ventilatory strategies. Because most preterm infants who have RDS require ventilatory support and BPD is a major morbidity of many forms of ventilatory support, the hope is to find a noninvasive method of ventilation for RDS that is both safe and effective.

The initial belief was that more complex ventilation strategies, such as high-frequency oscillatory ventilation, might decrease the risk of developing BPD. However, when optimal lung volume strategies are used, there is no difference between conventional ventilators and high-frequency ventilators in terms of pulmonary and nonpulmonary outcomes. A Cochrane review on this subject from 2007 confirmed the lack of clear evidence for elective use of high-frequency ventilation over conventional ventilation because no difference was documented in mortality between the two modes of ventilation at 30 days or at term-equivalent age. Patient-triggered ventilation is a form of conventional ventilation that includes synchronized intermittent mandatory ventilation, assist control, and pressure support. Studies have shown that patient-triggered ventilation has benefits over conventional ventilation and high-frequency ventilation in terms of a decreased duration of mechanical ventilation and decreased number of days on oxygen. However, there was no significant difference in terms of a decrease in lung injury between the three ventilation strategies.

The noninvasive ventilation strategy of nCPAP is believed to work by improving oxygenation without

increasing PaCO_2 through the stabilization and recruitment of collapsed alveoli. The idea is that nCPAP will help to achieve the adequate FRC that is necessary to avoid the development of RDS because increased FRC means increased alveolar surface area and less intrapulmonary shunt. The avoidance of endotracheal intubation saves the infant from the barotrauma and volutrauma seen with the use of mechanical ventilators. A Cochrane review from 2002 states that although a higher rate of pneumothorax was seen, there was an overall reduction in respiratory failure and mortality in preterm infants who had RDS and were treated with nCPAP. Large randomized, controlled trials to evaluate this possibility are underway.

The COIN trial (continuous positive airway pressure or intubation at birth) is a recently published randomized trial addressing whether the use of nCPAP shortly after birth would decrease the rates of death and BPD (defined as the need for oxygen at 36 weeks gestational age). A total of 610 infants from gestational ages 25 to 28 and 6/7 weeks were randomized at 5 minutes after birth to receive either nCPAP or intubation and mechanical ventilation. Outcomes between the two groups were assessed at 28 days, 36 weeks gestational age, and before discharge. There was a significantly lower risk of death or need for oxygen at 28 days in the nCPAP-treated infants, but early nCPAP did not significantly decrease the rates of death or BPD compared with intubation and ventilation at 36 weeks gestational age. Infants in the nCPAP group required fewer overall days of ventilation, but also had a significant increase in pneumothoraces compared with mechanically ventilated infants. The overall conclusion of the study was that early nCPAP was not detrimental to preterm infants whose gestational ages were between 25 and 28 and 6/7 weeks.

COMPLICATIONS AND TREATMENT OF RESPIRATORY DISTRESS SYNDROME

A major pulmonary complication of RDS is the development of BPD, which is generally defined as the need for oxygen supplementation at 36 weeks' corrected gestational age. Importantly, BPD is not caused by RDS; rather, it can be the result of the many treatments of RDS. The "new BPD," a term coined by Jobe in 1999, describes a syndrome that results from processes that interfere with lung development, not a syndrome resulting only from injury. These processes can include chorioamnionitis, oxygen administration, high tidal volumes, mechanical ventilation, postnatal sepsis, and postnatal corticosteroids. Accordingly, it is possible to develop BPD without having RDS, but BPD absolutely can occur in preterm infants who developed and were treated for RDS. Other complications of RDS in the preterm infant include IVH, patent ductus arteriosus, sepsis, and pulmonary hemorrhage, which likely result from a combination of prematurity, RDS, and its treatments.

Complications from the treatments for RDS are inevitable, but based on risk-to-benefit ratios of the treatments, the complications are mostly tolerable. Antenatal steroids do not have true short-term complications when examined in meta-analyses; there has been no associated increase in maternal death, maternal infection, fetal death, neonatal CLD, or neonatal birth weight. Concerns of decreased birth weight as well as trends toward increased incidence of IVH and long-term adverse behaviors have been voiced with the use of multiple repeat doses of antenatal steroids, but never consistently proven. Interestingly, in a 30-year follow-up of infants who received antenatal corticosteroids, no change in adult size or blood lipid or cortisol concentrations was documented, but there was a slight increase in the incidence of insulin resistance. These results may have implications for the hypothesis of the fetal origins of adult disease.

Mild complications of surfactant administration may include transient oxygen desaturation, apnea, and bradycardia, but such complications typically improve rapidly. More serious complications include endotracheal tube blockage and pulmonary hemorrhage. After administration, surfactant may distribute unevenly to only one lung or certain lobes. A second dose generally follows the same course as the first, which can lead to continued atelectasis of certain areas of the lungs. As mentioned, natural

surfactant administration causes an increase in grade 1 and 2 IVH compared with synthetic surfactant. Finally, after surfactant administration, the clinical signs of a PDA may develop earlier in the clinical course.

Complications of mechanical ventilation are not specific to infants being treated for RDS. Air leak syndromes, including PIE and pneumothorax, are more common when the poorly compliant lungs in RDS are mechanically ventilated. Pneumothorax is also associated with the use of nCPAP.

LONG-TERM PROGNOSIS

Survival of infants who have RDS has improved greatly with the use of antenatal steroids and SRT. Preliminary data in infants treated with antenatal steroids suggest the possibility of less neurodevelopmental delay. Overall, however, information regarding neurodevelopmental outcomes in the preterm infants treated for RDS is lacking, and long-term follow-up studies are needed.

CHAPTER 13

Mechanical Ventilation of Newborns: Current Perspectives

Sunil Sinha, Samir Gupta

Despite increasing interest in continuous positive airway pressure (CPAP) and other forms of noninvasive respiratory support, mechanical ventilation remains the mainstay of treatment of babies with respiratory failure. This saves life, even in the smallest of the babies born with extremely low birth weight but also causes a number of iatrogenic complications which limits their short- and long-term outcomes. Much has been learnt since then about the pathophysiology of ventilator induced lung injury (VILI)¹ and in response, newer modes of ventilation have been devised in order to try and minimize this. Whatever method is used, the goal of mechanical ventilation remains the same, which is to optimize tidal volume delivery, reduce the work of breathing and avoid iatrogenic complications.

A variety of newer modes of ventilation are now available on the neonatal units but they often cause confusion, as different nomenclatures have been used to describe the same thing. This has been made worse by the manufacturing industry that often chooses the term arbitrarily. It is therefore best to understand first the difference between various ventilatory modalities these newer ventilators can offer. This is made easier if one uses a classification of ventilatory devices based on a hierarchical system.²

At any one time, a ventilator can only work by using pressure or volume as control mechanism (called control variable or parent mode), which is set by the clinician. Most machines now provide the facility to operate the ventilator in either pressure or volume control mode. Both pressure and volume controlled modes have their inherent advantages and disadvantages and not surprisingly some of the newer ventilators have combined the desirable features of both (hybrid modes, see below).

In either mode, whether controlled by pressure or volume, the ventilator breaths can be delivered in a variety of ways. For this, the ventilator needs to know when to start inspiration, when to limit or sustain inspiration and

then when to end inspiration and cycle to the expiratory phase. These are known as the phase variables (daughter modes) which are interchangeable and can be set by choosing time, flow, pressure or volume. Modern ventilators allow the clinician therefore to create and deliver different breath types by using different modalities to trigger and regulate the phases of ventilation. For example, in traditional time-cycled, pressure limited (TCPL) mode of ventilation, pressure is used to limit the inspiratory flow and time is used to cycle inspiration into expiration. In more modern modes such as pressure support ventilation (PSV), pressure is used to limit inspiratory flow, but it is inspiratory flow, rather than time, that is used to cycle inspiration into expiration (known as flow cycling). These newer modalities are made possible by the use of sensitive flow sensors in conjunction with fast microprocessors running advanced software algorithms.

The following section describes the differences between the pressure-targeted and volume-targeted modes, including hybrid modalities such as volume-guarantee (VG), volume assured pressure support ventilation (VAPS) and pressure regulated volume control (PRVC).

PRESSURE VERSUS VOLUME-CONTROLLED MODES

Pressure-controlled or pressure-targeted modes allow the clinician to set the peak inspiratory pressure to deliver a flow of gas into the chest along a pressure gradient. As the lungs become filled with gas, the pressure gradient between ventilator and alveoli drops, and so does the flow, until a point is reached when the delivered pressure equals the airway pressure, when flow stops. Although the pressure is fixed, Pressure-control, however, does not guarantee consistent tidal volume delivery. This depends on the lung compliance. Thus, tidal volume delivered will be

lower when lungs are stiff but as compliance improves, the tidal volume delivered at a given pressure also improves. Therefore, in the context of surfactant deficient lung disease, the clinician must anticipate the tendency to over-distend the lungs as compliance improves, either with time or in response to treatment, such as exogenous surfactant administration.

In contrast, volume-controlled modes, the ventilator asks for a set tidal volume to be delivered and machine will deliver this regardless of the pressure required to do so. Therefore, when lungs are less compliant, the ventilator will generate higher peak pressures to achieve set volume but will reduce the pressure as compliance improves, always attempting to maintain the target tidal volume as set by the clinician. This rise in pressure (PIP) often used to cause anxiety to the clinicians but it must be realised that in context of efficacy and safety of ventilation, it is the volume (Volutrauma) and not the pressure (Barotrauma) which is more important.³

The flow waveform, as in the manner in which the flow is delivered to the patient, also differs between these two modes. With pressure-controlled modes, the flow accelerates rapidly until set pressure is reached, resulting in rapid filling of the lung in early inspiration. In contrast, volume-controlled ventilation produces a square flow waveform, in which alveolar filling is slow and peak pressure and volume are achieved at the end of inspiration. These different types of inspiratory flow delivery have inherent advantages depending on the pathophysiology of the lung. For example, pressure-targeted modalities are “front-end loaded” and may be more effective in treating stiff, atelectatic lungs, whereas in volume-controlled mode, it is “back-end loaded” and might work better in high lung volume states or where the disease is more varied.

Cochrane review looking at 693 infants from twelve randomized trials (nine parallel trials and three crossover trials) found the use of volume targeted modes resulted in a reduction in the combined outcome of death or bronchopulmonary dysplasia (typical RR 0.73 (95% CI 0.57 to 0.93), reductions in pneumothorax (typical RR 0.46 (95% CI 0.25 to 0.84), days of ventilation (MD -2.36 (95% CI -3.9 to -0.8)), hypocarbia (typical RR 0.56 (95% CI 0.33 to 0.96), and the combined outcome of periventricular leukomalacia or grade 3-4 intraventricular hemorrhage (typical RR 0.48 (95% CI 0.28 to 0.84). Infants ventilated using volume targeted ventilation modes had reduced death and chronic lung disease compared with infants ventilated using pressure targeted modes.⁴ Of all the studies included in the meta-analysis, the only one to provide longer term data with regards to neurodevelopmental and general health outcomes were from our own unit. This study looked at 109 children, of whom 94 survived to discharge and found that the efficacy of volume-controlled ventilation in very preterm and very low birth weight

babies appeared to be maintained on long-term evaluation.⁵

HYBRID MODES

Attempts have been made to combine the features of both pressure-targeted and volume-controlled ventilation resulting in a number of hybrid modes. These include volume-guarantee (VG), pressure regulated volume control (PRVC) and volume assured pressure support (VAPS). They are primarily pressure-controlled modes of ventilation but make use of a computer controlled algorithm in order to adjust the rise and fall of pressure to produce tidal volume delivery, using expired tidal volume measures of previous breaths to calculate the pressure requirements to achieve set volume. Volume assured pressure support ventilation makes within the breath (intrabreath) adjustment of pressure and/or inspiratory time until the desired volume has been provided.

VOLUME GUARANTEE VENTILATION

Volume guarantee™ ventilation, available on Draeger Babylog® 8000 ventilators, can be best described as a dual loop synchronized mode that delivers time cycled pressure limited breaths but allows the pressure to be adjusted to deliver a tidal volume in the range as set by the clinician. It achieves this by use of an auto feedback mechanism based on expired tidal volumes of previous breaths. The maximum pressure limit is set about 20 percent above the pressure needed to deliver this tidal volume constantly.

Potential advantages of Volume guarantee™ include less risk of volutrauma as the clinician set tidal volume is not exceeded when lung compliance improves, reduced peak pressures when baby makes significant contribution to tidal volume thus reducing chances of barotraumas, more stable tidal volume delivery and autoweaning of peak inspiratory pressures, thus protecting against barotrauma. The feedback loop, however, may have limitations. As adjustments to PIP are made in small increments to avoid overcompensation and are based on the exhaled tidal volumes, the delivered tidal volume cannot compensate for large breath to breath fluctuations (such as with large leaks).

Volume guarantee™ is the most widely used method of providing volume targeted ventilation, but not so well studied in randomized clinical trials. Of the published trials of VG, most are in forms of small crossover trials relating to endpoints based on short-term physiological changes. There is a lack of published data about the relevant long-term clinical outcomes. Cheema and Ahluwalia first investigated the feasibility and efficacy of Volume guarantee™ in 40 premature newborn infants (mean birth weight 1064 gm, gestation 27.9 wk) with symptoms of respiratory distress, in a four hour cross over trial. They

found that the mean peak inspiratory pressure and mean airway pressure using VG with either synchronous intermittent positive pressure ventilation (SIPPV) or synchronous intermittent mandatory ventilation (SIMV) was lower than that with either SIPPV or SIMV alone. No untoward effects were noted during the study period. VG as used in this study seemed to be a feasible ventilation mode for preterm neonates and achieved equivalent gas exchange using statistically significant lower peak airway pressures, both during early and recovery stages of RDS.⁶

VOLUME ASSURED PRESSURE SUPPORT VENTILATION

This mode is available on the VIP Bird Gold® infant/ pediatric ventilator and can be best described as variable flow volume ventilation and blends pressure support ventilation and volume controlled ventilation. A guaranteed tidal volume delivery is provided with each breath. Each breath starts as a variable flow pressure support breath. The ventilator will measure the delivered tidal volume when the inspiratory flow has decelerated to a minimum set level. If the delivered tidal volume equals or exceeds the set tidal volume, the pressure support breath is allowed to continue and is flow cycled. If the targeted tidal volume is not achieved the breath changes to a volume controlled breath with constant flow waveform and inspiration is continued till the set tidal volume is delivered.

PRESSURE REGULATED VOLUME CONTROL

Pressure regulated volume control (PRVC) is another mode of ventilation which attempts to combine the benefits of pressure limited and volume control ventilation. This is available on Servo 300A and the Servo-i ventilators (Maquet). It is a flow cycled mode that offers the variable flow rate of pressure control ventilation with a targeted tidal volume. Like volume guarantee, PRVC is also a form of closed loop ventilation in which pressure is adjusted according to tidal volume delivered. The new Servo-i ventilator features y-sensor measurements ensuring better measurement and more accurate delivery of set-tidal volume.

The clinician sets a target tidal volume and the maximum pressure to deliver the tidal volume. The micro-processor of the ventilator attempts to use the lowest pressure with a decelerating flow waveform to deliver the set tidal volume. The first breath is delivered at 10 cm H₂O above peak end expiratory pressure (PEEP) and is used as a test breath to enable the microprocessor to calculate the pressure needed to deliver the set tidal volume based on the patient's compliance. The next three breaths are delivered at a pressure of 75 percent of the calculated pressure needed. If targeted tidal volume is not delivered, the inspiratory pressure

is increased by 3 cm of H₂O for each breath till the desired tidal volume is reached. If targeted tidal volume is exceeded the inspiratory pressure is decreased by 3 cm of water. Inspiratory pressure is regulated by the ventilator between PEEP and 5 cm H₂O below the clinician set upper pressure limit.

In PRVC, the pressure is adjusted on the average of the previous four breaths and so variations in delivered tidal volume could still occur.

SYNCHRONISED MODES OF VENTILATION

As described earlier, both pressure and volume-controlled parent modes can be delivered in a variety of ways by using different phase variables. This section describes the commonly used synchronized modes in newborns.

SYNCHRONIZED INTERMITTENT MANDATORY VENTILATION

In this mode, the ventilator attempts to synchronize the onset of delivering a breath to the baby with the onset of a spontaneous patient breath. However, only a set number of breaths will be delivered by the ventilator according to the breath rate as set by the clinician. For example, if the rate was set at 40 breaths per minute, the ventilator will deliver 40 synchronized breaths to the baby, and will try and deliver these evenly throughout the baby's breathing cycle. It achieves this by setting breath periods, or timing windows, which are longer with slower rates. The first time the patient initiates a breath within a timing window, the ventilator will support that breath. If the patient takes another breath within the same timing window, this breath will not be supported, or will be supported only at the baseline (PEEP) level. If the baby was to breathe at a rate lower than the set rate, or has an apnea, then intermittent mandatory breaths will be delivered at the set rate. The clinician can set the peak inspiratory pressure if pressure targeted, or tidal volume, if volume targeted. The clinician also sets the inspiratory time, flow and SIMV rate.

In this sense, there is only marginal improvement in SIMV design as compared to conventional IMV. Most of the parameters are still set by the clinician; hence the chance of asynchrony is still present.

Most clinicians prefer SIMV as a weaning mode (at slow set rates), as it provides only partial ventilator support as baby can breathe spontaneously between assisted breaths. By noting the tidal volumes generated by the unsupported breaths, the clinician can judge suitability for extubation. This however can also be a drawback. As these breaths are not supported beyond PEEP, the work of breathing becomes harder on slow rate SIMV, especially as the baby is breathing to fight the high resistance of the endotracheal tube.

PRESSURE SUPPORT VENTILATION

To overcome this drawback, pressure support ventilation (PSV) can be combined with SIMV to provide additional support to spontaneous breaths alongside the synchronized mandatory breaths. PSV aims to support each spontaneous breath with additional pressure in order to overcome the resistance encountered from a narrow endotracheal tube and the dead-space of the ventilator circuit.⁷ With PSV, the patient controls the onset and end of inspiration (flow cycles) and thus inspiratory time. The mode also provides variable inspiratory flow as compared to fixed flow settings (such as in time-cycled pressure-limited modes) to provide a flow waveform synchronized to what the patient is attempting to achieve. The clinician is only left to set the peak inspiratory pressure provided. PSV cannot be used as a mode on its own as, unlike A/C, it does not provide a backup rate in cases of apnea or insufficient patient flow to trigger support. It is more commonly married with SIMV to provide effective weaning without tiring the patient out, and allows observation of respiratory drive before extubation.

ASSIST-CONTROL VENTILATION

In Assist-control ventilation also known as A/C ventilation, patient triggered ventilation or SSIPV on Draeger ventilator, the ventilator attempts to identify when the patient initiates a breath and if the patient's effort exceeds the trigger threshold, the ventilator will deliver a mechanical breath. If the patient is unable to trigger or is breathing below the set backup rate, a ventilator-delivered breath will be provided. In this mode, every patient-triggered breath beyond a threshold will be supported, regardless of the rate. Therefore, if the patient is constantly breathing above the set backup rate, reducing this value will have no effect. Patient triggered ventilation has an advantage over SIMV in that it supports every breath that meets the trigger threshold, thereby providing adequate minute ventilation with minimal work of breathing. Once again, PTV can be either time- or flow-cycled, but only the latter produces both inspiratory and expiratory synchrony.

PROPORTIONAL ASSIST VENTILATION

Proportional assist ventilation (PAV) is a fully adaptive mode which attempts to provide a breath in total synchrony with the patient. This is not only with regards to initiation and end of a breath but the ventilator will also adapt the intrainspiratory flow to provide a breath waveform that matches what the patient is attempting to do. In order to achieve this, the ventilator continuously measures the respiratory effort of the baby, adjusting pressure and flow in a proportionate way. Whereas in PTV, the clinician imposes peak inspiratory pressure, pressure rise time, and duration of lung inflation, in PAV, this is all determined by

what the patient is attempting actively during the cycle of a breath. The clinician is only left to set the 'gain' of this enhancement, and this brings about the idea of resistance and elastance. Resistance being the sum of tissue resistance (friction from lung tissue moving against each other) and airway resistance (the frictional resistance of the airways to flow of gas) and can be derived from the pressure difference (in cm H₂O) over flow (in l/min). Elastance is the reciprocal of compliance and is the tendency of a hollow organ to recoil towards its original dimensions upon removal of distending force. The gain that can be set is that of resistive unloading which is the work applied to overcome the resistance during inspiration, and elastic unloading, being the work applied to overcome the elastic resistance to inflate the lungs.

Clinical data regarding PAV is limited. One trial involving 36 very low-birth-weight infants found PAV to maintain similar gas exchange to more traditional IMV and patient triggered modes but with smaller pressures (15 to 44% reduction).⁸ Another paper highlights the problems that can be encountered with PAV by subjecting it to a series of *in vitro* tests. Artificial lung models were developed to mimic three different lung pathologies (respiratory distress, bronchopulmonary dysplasia and meconium aspiration syndrome). This study noted oscillations seen in airway pressure waveforms due to autotriggering, occasionally resulting in high peak pressures. There was also a significant delay seen between the onset of a breath and the ventilator initiating a mechanical breath. This was up to 100 milliseconds, which equates to a third of the baby's inspiratory breath left unsupported.⁹

NEURALLY ADJUSTED VENTILATORY ASSIST

Neurally adjusted ventilatory assist is described as mechanical ventilation controlled by brain signals or more specifically, vagus nerve stimulation of the diaphragm that might help to improve the synchrony between ventilator and patient. The act of breathing depends on rhythmic discharge from the respiratory center of the brain. This discharge travels along the phrenic nerve, excites the diaphragm, which leads to muscle contraction, negative pressure in the airways and inflow of air into the lungs. Traditionally, the ventilator detects flow generated by the patient from a sensor located somewhere between the endotracheal tube and the ventilator. NAVA attempts to capture the initiation of a breath at its onset from the respiratory centers in the brain, with the aim to provide improved synchrony. As the ventilator is cycled as soon as neural inspiration begins, mechanical coupling between the muscles of respiration and the ventilator should be improved. In addition, the level of assistance provided during inspiration is determined by the patient's own respiratory center demand.

One paper in 2009 looked at patient-ventilator interaction with neurally adjusted ventilatory assist in seven very low-birth-weight infants with an average birth weight of 936g (range 676–1266 g); gestational age 26 weeks (range 25–29). They were studied before and after extubation, initially during conventional ventilation, and then NAVA. They demonstrated that during conventional ventilation, the mean trigger delays were not different from NAVA, however 13 ± 8.5 percent of ventilator breaths were triggered on average 59 ± 27 ms prior to onset of diaphragmatic electrical activity. Conventional ventilation also cycled-off prior to NAVA (120 ± 66 ms prior, $p < 0.001$). Neural expiratory time was longer ($p = 0.044$) and respiratory rate was lower ($p = 0.004$) during NAVA. It was concluded that in low birth weight infants, NAVA can improve patient-ventilator interaction, even in the presence of large leaks.¹⁰ However, this was a very small study and further trials are required on our preterm population in order to determine its clinical usefulness and safety.

CONCLUSION

Although most clinicians still use their own preferred method, they should keep aware of new developments in the field of mechanical ventilation. Whatever ventilation modality is used, it is important to understand that the respiratory failure in newborns is a multisystem disease. Good outcomes will be determined by providing appropriate multiorgan support such as adequate nutrition, cardiovascular support and protection against infection. It should also be understood that respiratory failure is a dynamic condition which may require a change in ventilatory strategy depending on the course of the disease.

CHAPTER 14

Mechanical Ventilation in Neonates

Pankaj Garg, Sourabh Singh

The care of sick neonates has significantly improved over last 3 decades. The most important factors have been better obstetric services (use of antenatal steroid, better fetal monitoring), good respiratory support (use of mechanical ventilation and surfactant), nutritional support (early initiation of enteral feeding and parenteral nutrition) and prevention of nosocomial infection. Out of all these, mechanical ventilation has been most attractive and “high tech” fancy field for all neonatologists and pediatricians. As a result many pediatricians now want to establish this modality at their center to provide better care. Though it is a healthy sign which will give good dividends in the long run, it is important to realize that mechanical ventilation is more of an art than science and one learns while doing it more often. All centers doing ventilation experience a learning curve and it is important to modulate according to the local needs but certain principles should always be followed.

It is not possible to discuss all aspect of mechanical ventilation here but certain important points would be discussed here.

Topics to be Covered

- How neonatal mechanical ventilation differs from pediatric ventilation.
- Basic infrastructure before starting mechanical ventilation.
- Which babies require ventilation?
- Various modes of ventilation.
- Starting, monitoring and weaning of ventilation.
- Supporting services.
- Nutritional management.
- Monitoring and follow up of ventilated babies.

NEONATAL VENTILATION VERSUS PEDIATRIC VENTILATION

Neonate is not a small child and the ventilation requirements and strategies vary. The main differences to be highlighted are:

- Neonatal ventilators should have a constant gas flow as normal respiratory rate of a neonate is much more than pediatric patients and they breathe spontaneously in between the ventilator breaths and intermittent gas flow increases their work of breathing.
- Though there are advantages and disadvantages of each type of ventilation, most neonatal centers use pressure controlled, time cycled ventilation in neonates against volume-controlled ventilation in pediatric patients. An exception can be chronic lung disease patient in which volume controlled ventilation may be desirable.
- CPAP mode of ventilation is much more effective in a number of neonatal respiratory disorders (commonest being HMD, apnea of prematurity) unlike in pediatric patients. There is renewed interest in CPAP as a mode as it has also shown to reduce the incidence of chronic lung disease.
- Most neonatal ventilation is short-term ventilation averaging 3 to 5 days.
- High frequency ventilation with its unique features is being used in many neonatal disorders.

BASIC INFRASTRUCTURE BEFORE STARTING VENTILATION

- *Personnel:* It is imperative to have round the clock coverage by a doctor well versed with ventilation (theoretical as well as practical experience of at least 3-6 months)

and specially trained nurses around the clock (with at least 3 month of training in a unit doing ventilation).

- Protocol book for departmental policy, procedures and day to day decision-making.
- *Facilities:*
 - Portable X-ray machine
 - ABG machine.
- Procedures to be mastered Intercostal tube drainage, arterial line cannulation, PN administration.

Which Babies Require Ventilation?

Exhaustive list of indications can be found in any textbook, but what is important to remember is that initiation of ventilation is mostly a clinical decision in face of respiratory failure (not maintaining normoxemia or saturation) or impending respiratory failure (maintaining of normoxemia with increased work of breathing). Blood gas value of low PaO_2 (<50 mm Hg) or high PaCO_2 (>50 mm Hg) sometimes may warrant ventilation despite not so evident clinical indication.¹

Various Modes of Ventilation

- CPAP
- IMV
- SIMV
- SIPPV
- High frequency ventilation.

CPAP was first used in neonates by Gregory in 1971 and was found very effective especially in preterm babies primarily because of its effect on improvement of functional residual capacity. Over years it has become clear to the medical fraternity that many neonates can be saved only by using CPAP alone. Later IMV became the most commonly used mode in neonatal ventilation. Synchronization came a little late in neonatal ventilation because of faster respiratory rate in neonates and hence a need of low response time for synchronization. The advent of microprocessor technology has made SIMV possible in neonates. Despite a number of theoretical benefits of SIMV over IMV (less barotraumas, less air leak syndrome), the only proven benefit in randomized controlled trials is reduced number of days on ventilator which in itself is a big advantage making it a useful mode in every neonate. Various sensors used for SIMV are flow sensor (in Drager 8000), pressure sensor (Siemens 300) and abdominal capsule (Infant star).² In SIMV mode, only a fixed number of breaths are synchronized and the baby may still take more number of spontaneous breaths which are not synchronized. In SIPPV mode, all the spontaneous breaths taken by the neonate are synchronized and hence the rate is decided by the patient. In both SIMV and SIPPV modes, the inspiration is synchronized but the expiration is not. In flow cycled ventilation, even the expiration can be synchronized and this mode is labeled different in different ventilators e.g. PSV in Drager ventilation. Hence

in PSV, both the rate and the inspiration time are decided by the patient. In all these modes, FiO_2 , PIP, PEEP and Flow are operator dependent.

High frequency ventilation with its unique features of low Vidal volume and high respiratory rate strategy has been shown to be of help in some patients of PPHN, congenital diaphragmatic hernia and air leak syndrome. The most common indication of use of HFO in our experience has been as rescue therapy when conventional ventilation is not able to achieve normoxemia.

Starting, Monitoring and Weaning from Ventilation

- Before starting any baby on conventional ventilation it is important to know normal values of neonatal respiratory function.

Tidal Volume ml/ kg	6-8
Compliance ml/ cm	2-3
H_2O / kg	
Resistance cm	20-40
H_2O /L/min	
Tidal pressure change (cm H_2O)	5-6
I: E ratio	1:2 to 1:6
Time constant	0.25 second
FRC	30 ml/kg
Desirable PaO_2	50-80 mm Hg in preterm 60-90 mm Hg in term
Desirable PaCO_2	35-45 mm kg in initial phase of ventilation Up to 60 mm Hg later
O_2 saturation	88-92% in preterms and 91-95% in term babies

- *Desirable specification of neonatal ventilator:* Preferably use those ventilators which give set and measured values, so we can be sure that baby is getting the same settings which we have set on ventilator. Preferably do not use those ventilators for ventilating newborns which are capable of ventilating pediatric and adult patients also. As these ventilators do not give correct values of delivered tidal volume in neonates.

Accurate and early control of FiO_2	0.21 to 1.00
PEEP	0 to 25 cm H_2O
Rate	0-120 per minute
Peak pressure	0 to 80 cm H_2O
Ti	0 to 60 sec
TE	0 to 30 sec
Constant gas flow	
Low compliance of the patient ventilator circuit (Use specified circuit by manufacturer)	
Humidification	
Monitors and alarms	

- *Steps of starting MV:*
 - Intubation (oxygen delivery during intubation very crucial) followed by IPPR by self-inflating mask to achieve adequate SpO_2 and chest expansion
 - Fixation of ET making sure that the tube doesn't slip in or out
 - Cutting ET to 4 cm beyond angle of mouth to decrease the dead space
 - Continue IPPR till connected to ventilator
 - Putting ventilation circuits (low compliance, preferably disposable) using gloves
 - Connected to O_2 and compressed air source (preferably central, stationed outside the unit)
 - Set humidifier temperature to 37°C or 39°C depending on type of humidifier. Closed system to deliver sterile water for humidification into the humidifier
 - Use circuits with heated wires, so that gases are always delivered at set temperature. Keeping heated wires in both inspiratory and expiratory circuits make it expensive and most units use heated wires in inspiratory circuits and water trap in expiratory circuit
 - Check the “set values” making sure that the desired setting will be delivered
 - Always set alarms. Most common reason of alarms is that their values are not set
 - Attach to endotracheal tube.
- Ventilatory setting depends primarily on the indication of ventilation, the peak pressure/ FiO_2 requirements judged by bag and tube ventilation.³⁻⁶
 - Ventilating a normal lung (indication apnea of prematurity or central depression): PIP 12-14 cm H_2O , PEEP 3-4 cm H_2O , FiO_2 0.21-0.25, RR 40-45 BPM, IT 0.3–0.35, Flow rate 6-8 L/mt
 - Ventilating a diseased lung
 - With low FRC (e.g. HMD) PIP 18-20 cm H_2O , PEEP 5-6 cm H_2O , FiO_2 depending on $\text{SpO}_2/\text{PaO}_2$, RR 50 to 60 bpm, IT 0.3 to 0.35 sec
 - With high FRC (e.g. MAS) PIP 18-20 cm H_2O , PEEP 2-3 cm H_2O , RR 30-40 bpm
 - We do not need to remember these values, these are rough guidelines, as each diseased lung is different. Clinically by observing chest rise and adequate air entry, we can adjust PIP values. In ventilators providing measured tidal volume (e.g. Drager babylog), we can adjust PIP, so that measured tidal volume lies between 4-6 ml/kg
 - PEEP is increased until retractions disappear. If while ventilating a baby PEEP is 5 and FiO_2 is 80 percent, this is wrong combination. We should try to recruit lung areas by increasing PEEP. Chest X-ray should be done within 30 minutes to look whether we are providing optimum PEEP. In CXR, lung should not be expanded more than 8 posterior intercostal spaces. If lung expansion is more, PEEP is decreased and if lung expansion is low, PEEP can be increased to recruit lung and decrease FiO_2 . In ventilators providing measured tidal volume (e.g. Drager babylog), if measured tidal volume decreases on increasing PEEP, PEEP is reduced.⁷
 - Drager babylog gives C20/C ratio which is the ratio of compliance of last 20 percent of lung expansion to total compliance. It should be more than 80 percent (0.08). If it is less, it indicates overinflation.⁸
- *Further evaluation on ventilation:*
 - It is important to remember that as all these values are empirical, we need to confirm whether we are adequately ventilating or not by doing blood gas analysis which should be done every 4 hours for first 24 hours and then depending on the progress of the disease. Value of minute ventilation at which adequate PaCO_2 values are obtained can be noted and alarms of minute ventilation can be set, thus reducing number of arterial blood gases. Normal values for minute ventilation are 160-200 ml/kg/min⁹
 - Taking care of hemodynamic status, nutritional status and infection prevention.
- *Clinical strategy of ventilation:*
 - To improve oxygenation
 - Increase PIP/ PEEP (look at chest rise, if not adequate increase PIP otherwise PEEP. If chest retractions, increase PEEP), increase IT, increase flow rate, increase rate in this sequence. All these parameters increase Mean Airway Pressure
 - Increase FiO_2
 - Improve ventilation
 - Increase TV (\uparrow PIP or decrease PEEP), increase RR thereby increasing minute ventilation.
 - Effect of individual variables
 - \uparrow PIP \rightarrow \uparrow MV (minute ventilation), \uparrow MAP (mean airway pressure)
 - \uparrow PEEP \rightarrow \downarrow MV, \uparrow MAP
 - \uparrow Ti- \uparrow MAP
 - \uparrow FiO_2 \rightarrow \uparrow Oxygenation
 - Arterial blood gases for monitoring ventilation: If PaO_2 is decreased and PaCO_2 is increased, then increase PIP and vice versa. If both PaO_2 and PaCO_2 is low, PEEP is increased and vice versa.
- *Trouble shooting during ventilation:* If a baby on ventilator, starts desaturating suddenly look for the following possibilities.^{10,11} Remember DOPE SIPP which stands for displacement, obstruction, pneumothorax, equipment failure, shock, infection, PDA, PPHN. Trained personnel and resuscitation equipment near the ventilated baby should always be ready. The causes can be related to baby or the ventilator including ventilator circuits. Quickly check that baby is not disconnected from ventilator (could occur in a active struggling baby

or while change of position or after taking weight) and ventilator is not disconnected from power supply. Hand ventilate the baby

- If air entry and breath sounds are decreased—then look for tubal displacement/tubal obstruction/pneumothorax
- If air entry and breath sounds improve by increasing pressure, look for partial tube block or worsening of lung disease (by doing CXR)
- If baby does not improve but breath sounds and air entry are normal, look for shock, PPHN, PDA
- If baby improves on similar pressures during hand ventilation, look for ventilator related problems/compressor/O₂ and air supply pressures (at least 50 psi)

We can check, set and measured parameters in most neonatal ventilators in case of acute deterioration. Look for following values:

- Difference in pressure
- Difference in FiO₂ (faulty blender)
- Look at graphs (help in tubal block, pneumothorax, etc.)
- % leak
- TV and MV changes.
- h. *Weaning from ventilation:* The weaning has to be a thinking process depending on the condition for which baby was ventilated, present ventilatory setting and hemodynamic status. Now aggressive weaning is followed to cut short duration of ventilation.^{12,13}

Weaning Strategies

- Reduction in PIP and FiO₂ should go hand in hand
- Reduction in rate, once PIP has been reduced to low levels 12 to 14 cm H₂O
- Faster weaning if the disease has recovered fast (e.g. HMD after surfactant administration, central depression after naloxone administration, delayed transition in asphyxiated neonates)
- Nasal IMV as soon as setting are not very high
- From IMV to SIMV as rates come down less than 40 bpm
- Extubation from SIMV rate of 20/mt to oxygen hood (shorter ventilation) or nasal CPAP (in case of prolonged ventilation >5 days)
- Prophylactic methylxanthines can be used in peri-extubation period in preterm neonates¹⁴
- No routine use of nebulization or steroids before/after extubation.

SUPPORTIVE SERVICES DURING VENTILATION

- a. Strict infection control strategies:
 - Use of disposable ventilatory circuits
 - Change of circuits every week or if visibly soiled
 - Closed system of adding water to the humidifier

- Proper hand washing techniques
- No routine ET suctioning (if resistance is displayed, do suction when resistance increase by more than 150%)
- Strictly measure the distance to which suction catheter is inserted to avoid formation of subglottic stenosis by repeated deep suction.
- b. Thermal homeostasis.
- c. Fluid and electrolyte homeostasis.
- d. Use tegaderm when applying tape to fix endotracheal tube to avoid abrasions on cheek after removal of tube.
- e. No routine use of antibiotics just because baby is ventilated.
- f. No routine sedation. Remember most common reason for agitation during ventilation is inadequate ventilatory support.

Nutritional Support

- Start enteral feeds at the earliest as early as D1 to D2 if baby is hemodynamically stable and does not have abdominal distention or abnormal residues. Remember ventilation is not a contraindication for baby to be on full feeds.
- Start parenteral nutrition if neonate is not expected to come on total feeds by D5 of life. Start amino acids with 3 to 3.5 gm/kg on D1 and intralipid at a rate of 1.5gm/kg which can be increased to 3 to 3.5 gm/kg depending on serum triglyceride levels (acceptable <200 mg%). It is very important to realize that nutrition support is the most important factor in successful extubation in babies on prolonged ventilator.

Family Support

Parents must be constantly kept informed regarding the condition of the baby, the possible time frame of recovery, the finances involved and the need of follow up even after discharge. Mother should work like a nurse to her baby apart from giving early stimulation and expressed breast milk.

MONITORING DURING MECHANICAL VENTILATION

- Assessment of ventilator gas exchange, oxygen transport and consumption
 - Continuous SpO₂ monitoring by pulse oximeter
 - Continuous TcCO₂ (transcutaneous CO₂ monitor)/Endotracheal CO₂ monitoring
 - Continues temperature monitoring
 - Continuous IBP monitoring
 - Intermittent blood gas monitoring
- Simultaneous monitoring of other systems and functions
 - CRT
 - CVS evaluation for PDA, CVP, ECHO
 - Biochemical stability

- Monitoring for complication
 - XRC for air leak, tube placement, collapse, BPD, cardiomegaly
 - Transillumination of chest for pneumothorax
 - Cranial USG for PVH, IVH, hydrocephalus
 - Infection – tracheal aspirates, blood cultures
 - Skin – avoid burns, abrasions, infections
 - Hb – maintain blood letting record, micro sample techniques
 - Eye check up for babies <32 weeks/ <1500 gm at 4 weeks
 - Catheter maintenance–infection, blockade, thrombosis.

Follow-up Program

It is very important to follow all ventilated babies for early detection and management of general morbidities (growth retardation, apnea, respiratory infection, aspiration) and CNS morbidities (neurodevelopmental, handicap, hydrocephalus, periventricular leukomalacia, cerebral palsy), hearing loss, speech problems, refractive errors, etc.

SUMMARY

Neonatal ventilation combined with other support services has definitely improved the survival of sick neonates. It is an art, which has to be learned over a period of time. It needs a team approach to provide good results. It is important to remember “LOVE” (laws of ventilatory efficiency):

- Know your ventilator well.
- Know the pathophysiology for which you are ventilating and choose appropriate strategy.
- Change your strategy according to change in pathophysiology.
- Other support services (nutrition, infection prevention, etc.)

It is important to combine it with other useful strategies like antenatal steroids, surfactant therapy, early ventilation, gentler ventilation and nutritional support, to provide optimum results.

CHAPTER 15

High Frequency Ventilation

Pankaj Garg, Saurabh Singh

Ventilation has been the cornerstone of the treatment of neonates with respiratory distress. In this era of surfactant and sophisticated conventional ventilation, there are still some neonates who can not be adequately ventilated or suffer problems related to the ventilation during the process of recovery. Therefore, respiratory insufficiency remains one of the major causes of neonatal mortality. Intensification of conventional ventilation with higher rates and airway pressure also leads to an increased incidence of barotrauma. The high shearing forces resulting from large pressure amplitudes damage lung tissue (volutrauma) and therefore incidence of chronic lung disease increases with the increase in the survival of preterm babies. It was hoped that high frequency ventilation with its unique features might resolve some of these desperate situations. Though this novel mode of ventilation has not universally shown the benefits but in expert hands it stands a chance of reducing the incidence of chronic lung disease and has definitely added another important weapon in the ventilation armamentarium with some unique advantages.

There are three types of HFV¹: Jet ventilation, high frequency oscillation (Sensor medics) and high frequency flow interrupters (Baby log and Infant star). These types are defined primarily by the way they create high frequency pressure and flow changes in the airways and whether they employ active or passive exhalation. Jet ventilators deliver a jet of gas through a specialized endotracheal tube directly into the trachea. Oscillators vibrate a volume of gas using a piston or diaphragm to compress and then rarefy the air mixture in the ventilatory circuit. Flow interrupters create a gas pulse by intermittently interrupting a high flow source. Only HFO employs an active exhalation phase. Jet ventilation is no longer in use in most of the centers. Rest of our discussion will be focused on the other two types of high frequency ventilation.

Since HFV was first described by Lunkenheimer in the early seventies in apneic dogs, this method of ventilation has been further developed and is now applied all over world.

CHARACTERISTIC FEATURES

In conventional ventilation oxygenation and ventilation are closely linked and ventilator adjustments to either will affect the other. In HFOV, they can be treated separately and optimized independently.

There are three distinguishing features of high frequency oscillatory ventilation—the frequency ranges from 5 to 50 Hz (300 to 3000 bpm), active inspiration and active expiration and tidal volumes about the size of the dead space volume.

The efficacy of HFV is primarily due to improvement in pulmonary gas exchange but it can also have favorable influence on respiratory mechanics and hemodynamics.

During conventional ventilation direct alveolar ventilation accomplishes pulmonary gas exchange. According to the classic concept of pulmonary ventilation the amount of gas reaching the alveoli equals the applied tidal volume minus the dead space volume. At tidal volumes below the size of the anatomical dead space this model fails to explain gas exchange.² Instead, considerable mixing of fresh and exhaled gas in the airways and lungs is believed to be the key to the success of HFV in ventilating the lung at such very low tidal volumes. The details of this augmented gas exchange are still not fully understood. The various suggested mechanisms are:

Augment Longitudinal Gas Transport and Enhanced Dispersion³

This is based on Taylor dispersion principle. In this process, an initially plane bounding surface between two gases

develops into a pike-shaped profile as the velocity of one of the gases increases (Fig. 1).

DIRECT ALVEOLAR VENTILATION

A small part of proximal alveoli is still ventilated directly. Hence, gas exchange takes place as in conventional ventilation.

Intra-alveolar Pendant

Different regions of the lung have different compliance and resistance. Therefore, neighboring units with different time constants are ventilated out of phase, filling and emptying at different rates. Due to this asynchrony these units can mutually exchange gas, an effect known as pedelluft (Fig. 2).

Effect on Respiratory Mechanics and Hemodynamics

The application of a high MAP will recruit additional lung volume by opening regions of the lung with poor inflation. An increase in compliance will result. At the same time, a better ventilation perfusion ratio with reduced intrapulmonary right to left shunting is observed. In PPHN, the rapid decrease in paCO_2 during HFV can reduce pulmonary vascular resistance.

The optimal lung volume strategy recruits alveoli and lung segments and once an optimal lung volume is achieved recruitment, lung volume and oxygenation can be maintained with a lower MAP (Fig. 3).

Fig. 1: Taylor dispersion: Boundary surface between two gases with different flow velocity. Gas exchange occurs at the boundary surface through lateral diffusion

Fig. 2: Intra-alveolar pendant during the next phase the alveoli mutually exchange gas

Fig. 3: Optimal lung volume strategy

CHARACTERISTIC PARAMETERS AND CONTROL VARIABLE OF HIGH FREQUENCY VENTILATION

Three parameters determine oscillatory ventilation. Mean airway pressure (MAP) around which the pressure oscillates, the oscillatory volume (TV) which result from the pressure swings and the oscillatory frequency (f).

- **MAP:** In CPAP + HFV mode, MAP equals the set PEEP level. When IMV ventilation cycles are superimposed as is possible in Dräger ventilator, MAP also depends on the PIP and the frequency. The crucial physiologic effect of such continuously applied inflation pressure is the opening of atelectatic lung areas, resulting in marked recruitment of lung volume.
- **Amplitude:** It ranges from 0 to 100 percent and influences the oscillatory volume directly. During HFV volumes similar to the dead space volume (2-2.5 ml/ kg) should be the target.
- **Oscillatory frequency:** The oscillatory frequency measured in units of hertz ($\text{hz} = 1/\text{s}$), influences the oscillatory volume and the amplitude depending on the ventilator type used. Normally, lower frequencies permit higher volumes.
- **Gas transport coefficient DCO_2** (a parameter used in Dräger ventilation): In conventional ventilation the product of tidal volume and frequency, known as minute ventilation, aptly describes pulmonary gas exchange. But in HFO, CO_2 elimination correlates well with DCO_2

$$\text{DCO}_2 = (\dot{V}\text{T})^2 \times f$$

$$\text{VT} = \text{oscillatory volume, } f = \text{frequency.}$$

As frequency is inversely related to tidal volume, a reduction in frequency most of times lead to increase DCO_2 .

CURRENT STATUS OF HIGH FREQUENCY VENTILATION

In newborns HFV has first been employed as a *rescue treatment* when conventional ventilation fails. There are very few controlled trials (total 4:2 in preterms and two in term and near term neonates), which address this issue and the results are summarized here. The HIFO trial⁴ didn't

show much advantage with the side effect of increased risk of IVH while the trial by Keszler⁵ and colleagues showed more rapid improvement in PIE and lower mortality rates. These trials were done at a time when surfactant and antenatal steroids usage was not on routine basis hence recent trials done by Clark⁶ and Engle appears more applicable to current times. Clark et al showed improved gas exchange and less treatment failure with HFV with no difference in CLD, IVH or death. Eigle et al⁷ showed similar results making more grounds for future studies to look for long term benefits which have been scanty till date. From a scientific viewpoint, the prospectively randomized studies represent the most valid approach to testing efficacy of HFV but from a clinical viewpoint, the data from sequential patient series provide justification for trials of HFV for infants failing to respond to CMV, because these reports demonstrate that there is an incompletely defined subset of infants who fail CMV and respond to HFV dramatically.

The second commonest place where HFV is used is when *barotrauma* has already occurred or is imminent, e.g. air leak syndromes (pneumothorax, PIE). There are theoretical reasons to believe that HFV leads to less barotrauma though published data has contradictory results.

Some centers have started using HFV as a *primary treatment for hyaline membrane disease in preterm neonates*. To date, there have been 15 randomized controlled clinical trials of elective use of HFV versus CMV for the treatment of premature neonates who have respiratory insufficiency or RDS.^{8,9} One additional study compares the use of HFV versus CMV in term and near-term infants. The data from these 16 randomized controlled trials of HFV have yielded conflicting results. Five of the 16 trials demonstrated that early elective use of HFV improved pulmonary outcomes, in particular, decreased the incidence of chronic lung disease, as compared with CMV. The 11 remaining trials showed no difference in pulmonary outcomes when using HFV versus CMV. Differences in high-frequency ventilators used, ventilation strategies, definitions of chronic lung disease, study populations, and study center experiences over time, as well as the inability to blind the treatment intervention, may be the derivation of such incongruent results regarding early use of HFV versus CMV. Likewise, some of the studies were conducted before routine use of exogenous surfactant.¹⁰ There is no evidence from the current review of the literature that elective use of HFV, in the form of HFOV or HFFI provides any greater benefit to premature infants who have RDS than CMV. The data are limited and the results are mixed as to whether HFJV may reduce the incidence of CLD. At this time, preferential use of HFV as the initial mode of ventilation to treat premature infants who have RDS is not supported. There are trends towards increase in all grades of IVH¹⁰ and in periventricular leukomalacia in earlier meta-analysis. The problem in this meta-analysis is that it is dominated by the large HIFI study¹⁰ which did not use the recommended high volume strategy (high MAP-high

PEEP) and surfactant was not available at that time. Subsequent studies most of which used high volume strategy and/or used surfactant, have not shown an increased rate of IVH. Caution is warranted in interpreting these results as the treatment is not blinded, the benefits and harms have not been reported in infants born at different gestational ages or of different birth weights and long-term effects are not yet known.

Use in PPHN

Review of the literature¹¹ supports the use of HFV with iNO to maximize oxygenation and treatment effects in hypoxemic respiratory failure, in particular in babies who have pulmonary hypertension.

Use in Treatment of Bronchopleural or Tracheoesophageal Fistula

The current literature lacks any randomized trials to support the use of HFV over CMV in the treatment bronchopleural or tracheoesophageal fistula.

Likewise, in cases of congenital hernia and during surgical correction, HFV has been successfully used as a primary treatment.

GUIDELINES FOR USE OF HIGH FREQUENCY VENTILATION

Principles of Operation

Currently available HFOV are easy to set up and use. There are few operator available controls, but they are very potent in their potential effects on pulmonary gas exchange.

Transition from Conventional Ventilation

In applying an open lung strategy, Paw is gradually increased by steps of 1 cm H₂O to 2 cm H₂O, with the goal of reducing the FiO₂ to less than or equal to 0.6 while achieving target oxygen saturation (SaO₂) values. During this phase, hemodynamics should be carefully monitored, and at the occurrence of a minimal decrease of blood pressures (i.e. more than 2 mm Hg in the preterm infant), airway pressures have to be reduced and the oxygen response conserved before eventually further increasing airway pressures again. Once appropriate saturation is achieved and FiO₂ could be lowered to less than or equal to 0.6, airway pressure should be reduced stepwise in increments of 1 cm H₂O to 2 cm H₂O (moving downward on the deflation limb of the pressure/volume curve that exhibits hysteresis) as long as SaO₂ can be maintained, the ultimate goal being to find the lowest pressure allowable to maintain "good" saturation. Chest radiography is recommended after finding the optimal Paw to ensure adequacy of lung expansion and avoid over-distention.

HFV: Start

MAP (PEEP): 2 to 5 cm above MAP of conventional ventilation, if necessary increase MAP until paO_2 improves, X-ray done after 30 minutes.

HFV frequency: Start with 10 Hz, adjust after seeing paCO_2

HFV amplitude: Start with 30 to 50 percent, watch thorax vibrations

HFV volume: 2 to 2.5 ml/kg

HFV: Continuation

Hypoxia	Increase MAP up to 25 cm H_2O , alternatively apply sustained inflation at low lung volume apply sigh maneuver every 20 minutes for 10-20 seconds at 10 to 15 cm H_2O above MAP
Hyperoxia	Reduce FiO_2 down to about 0.5, very carefully decrease MAP
Hypercapnia	Increase DCO_2 (by decreasing frequency or increasing amplitude)
Hypocapnia	Decrease DCO_2 (by increasing frequency or decreasing amplitude)
Overinflation	Reduce MAP, decrease f, discontinue HFO
Hypotension	Volume expansion, inotropes, reduce MAP, discontinue HFO

HFV failure—when ventilation deteriorates even at 5Hz, maximal amplitude and optimal MAP, switch back to conventional ventilation. If ventilation/oxygenation doesn't improve within 2 to 6 hours you should consider the patient a non-responder to HFV.

Weaning from Oscillatory Ventilation

Weaning from HFO should be a slow and thoughtful process. Weaning depends on the basic lung pathology for which HFO was started. If it is an overinflated lung or with atelectasis, reduction of MAP takes priority over FiO_2 . In all other situations FiO_2 is reduced first. Reduction of FiO_2 /MAP should be slow remembering that a change in MAP does not instantaneously change oxygenation. In a stable clinical situation one should wait 30 to 60 minutes before assessing the effect of the new setting. When FiO_2 is reduced to 0.5, MAP is reduced by 1 to 2 cm H_2O at a time until 8 to 9 cm H_2O . Amplitude is reduced to 40 to 50 percent and frequency kept >10 Hz depending on the initial settings. On these settings, IMV breaths are increased gradually, which means reduction in time on HFO. Gradually IMV rates are increased to 25 breaths per minute at which stage, HFO can be switched back to conventional ventilation.

Monitoring During HFO

- Vital parameters must be closely monitored. HFO at high MAP >10 cm H_2O can reduce cardiac output as evidenced with the help of echocardiographic

contractility of myocardium and quantitative evaluation of tricuspid insufficiency. Particularly in severely ill infants it is wise to measure the CVP regularly. A notable increase can herald cardiorespiratory decompensation at very high airway pressure. Also prolonged CFT and reduced urine output may indicate compromised cardiac function.

- The state of lung expansion has to be assessed by periodic chest radiographs. It is optimal on the 8th to 9th posterior rib level. When IMV is superimposed on HFV it is important to take the radiograph in the expiratory phases of the mandatory cycles.
- First blood gas should be within 15 to 20 minutes after starting HFO to see paCO_2 . HFO can reduce paCO_2 very fast with its detrimental effects like IVH and periventricular leukomalacia. Frequent blood gases should be done to keep paCO_2 between 35 to 45 mm Hg H_2O . Preferably transcutaneous paCO_2 monitoring should be done. With low tidal volume EtCO_2 readings are often erroneous.
- In-line suction must be used. Press *Stop* button briefly on SensorMedics while briefly inserting and withdrawing catheter. PAW is maintained throughout.

Rationale for pausing: The oscillator causes a pressure pulse in the airways. When suctioning if the SensorMedics is not turned off the secretions get pushed back down because of this pulse pressure. So you are having ineffective clearance of secretions. There is also the potential of air trapping with active piston movement.

Strategies for Various Lung Diseases

- HFV for diffuse homogeneous lung diseases (HMD, diffuse pneumonia, bilateral lung hypoplasia)
 - Goal:* Lung expansion, less barotrauma
 - Begin with MAP 2 to 5 cm H_2O above that of conventional ventilation
 - Increase MAP until paO_2 rises, or CVP increases, signs of over-inflation appear
 - Reduce FiO_2 to 0.3 to 0.5, then continue weaning
 - Settings of frequency and amplitude depend on the necessity of CO_2 removal.
- HFV for nonhomogeneous lung diseases (Focal pneumonia, pulmonary hemorrhage, meconium aspiration, unilateral lung hypoplasia, BPD)
 - Goal:* Improved oxygenation and ventilation at minimum MAP
 - Risk:* Partial overexpansion
 - Begin with MAP like or below that on conventional ventilation
 - HFV frequency low, e.g. 7 Hz
 - Then increase MAP slowly until paO_2 slightly rises; keep MAP constant.
- HFV for air leaks (Pulmonary interstitial emphysema, pneumothorax)

Goal: Improved oxygenation and ventilation at minimum MAP, accept lower paO_2 and higher paCO_2

- Don't superimpose IMV for the risk of further barotrauma
- Place the baby on the side of air leak
- Adjust MAP below that of conventional ventilation, if possible
- HFV frequency low, 7 to 8 Hz
- Reduce pressure prior to FiO_2
- Continue HFV for 24 to 48 hours after improvement.

• **HFV for PPHN**

Numerous authors have reported effective therapy of PPHN with HFV. Continuous application of high MAP, uniform opening of the lungs, diminished pulmonary vascular resistance, improved ventilation perfusion match are the suggested mechanism, which help. The favorable oxygenation along with improved CO_2 reduction additionally counteracts pulmonary vasoconstriction.

Goal: To optimize lung volume and perfusion; to improve hypoxia and hypercapnia while minimizing barotrauma.

- Before switching to HFV, hypovolemia and hypotension should be corrected
- HFV frequency <10 Hz
- HFV amplitude 100 percent
- MAP on the level of conventional ventilation, increase as needed for oxygenation
- IMV rate 0 to 15 bpm
- Reduce FiO_2 prior to MAP
- Maintain HFV 24 to 48 hours after recovery
- Always: Minimal handling, use sedation or relaxation.

Complications and Side Effects

- *Irritation:* Babies are often irritated by HFV at first and require deeper sedation. However, they often become quite in accordance with improved oxygenation and adequate paCO_2 levels.
- *Secretion:* Even small amount of secretions or foam after surfactant administration can considerably affect the efficacy of HFV. This is reflected in a decrease in oscillatory volume. Sufficient humidification of inspired gas is mandatory.
- *Hemodynamics:* Often a slight reduction in heart rate and refractory apnea is attributed to an increased vagal activity during HFV. High MAP can compromise both venous return to the heart and cardiac output as well as lead to an increase in pulmonary vascular resistance.
- *Intracranial hemorrhage:* Whether HFV promotes IVH or not has been discussed for a long time. The critical

condition of the patients is probably connected with this presumed effect. More recent studies, during which HFV was applied early, don't report a higher incidence of such complications as compared to conventional ventilation.

- *Overinflation:* Pulmonary overinflation in obstructive lung diseases (e.g. MAS) is the most frequent complication and cause of failure of oscillatory ventilation. Here air trapping may occur especially with higher frequencies and inappropriate I:E ratio. With improved HFO strategies both barotrauma and air leaks have been reduced.
- *Necrotizing tracheobronchitis:* Local irritation leading to necrosis of the tracheobronchial systems can occur as complication of HFJV but also of HFOV and conventional ventilation. Inadequate humidification and excessive MAP are named as pathophysiological causes. In recent studies no significant differences have been observed in two types of ventilation.
- *BPD:* With respect to the development of BPD and CLD, the published literature shows contradictory results.¹²
- *Others:* In some cases air embolism has been reported. This complication can also occur during conventional ventilation with high pressures.

Contraindications

Pulmonary obstruction is the only relative contraindication known. There is no publication that IVH or coagulopathy are contraindication of HFV.

Limitation of HFV

The success of HFV largely depends on the power of the HF ventilator, which is characterized by the size of the oscillatory volumes at sufficiently high frequencies. Compliance and dead space of the patient circuit has crucial impact. With a low compliant circuit, the oscillatory volumes can be considerably increased. Presently available HFV (Babylog 8000, Infant star) allow ventilation with infant up to 2 kg. Depending on weight and lung mechanics, one should however expect occasional failure due to insufficient oscillatory volumes in the upper frequency range. SensorMedics is very strong oscillator and can effectively oscillate a 30 kg patient (Figs 4A and B). In SensorMedics high frequency ventilator, pressure (Amplitude) controls CO_2 elimination and continuous distending pressure controls O_2 . Continuous distending pressure is bias flow dependent. Higher flow leads to higher CDP. Adjust knob is green control line and limit knob is blue control line. Inspiratory time is adjusted at 33 percent to prevent air trapping. Piston is centered with the help of piston centering knob.

Figs 4A and B: SensorMedics machine

CONCLUSION

Most causes of neonatal respiratory failure require mechanical ventilation are amenable to treatment with HFOV or CMV. For either technique to be successful, lung volumes need to be optimized for the underlying condition, and pressure exposures must likewise be similarly regulated. Only by the careful application of the chosen technique can ventilator induced lung injury be avoided. HFV application has also highlighted the importance of man behind the machine which makes the difference. Studies coming from some centers have consistently shown better results than from some other centers. It appears that HFV is now a salient member of the still growing armamentarium available for taking care of babies with respiratory distress.

Continuous Positive Air Pressure and Noninvasive Ventilation

Pankaj Garg, Ankur Kumar

INTRODUCTION

Continuous positive air pressure (CPAP) is positive pressure applied to the airways of a spontaneously breathing baby throughout the respiratory cycle. Attitudes to the relative merits of intubation and ventilation and noninvasive ventilation CPAP and nasal intermittent positive pressure ventilation (NIPPV) have evolved since Gregory's study. Advocates of noninvasive ventilation cite the reduced risk of trauma to the larynx and trachea, infection and acute and chronic lung disease with this form of support. The rationale for use of CPAP is to support the airways and avoid alveolar collapse to a level below FRC.

How does CPAP work?

Continuous positive air pressure (CPAP) supports the breathing of premature infants in a number of ways.^{1,2} The upper airway of the preterm infant is very compliant and therefore prone to collapse. CPAP splints the upper airway and therefore reduces obstruction and apnea. CPAP assists expansion of the lungs and prevents alveolar collapse. In doing so it reduces protein leak and conserves surfactant.

Physiology and how CPAP Helps

Preterm babies cannot maintain FRC due to various reasons:³

- Not able to generate enough negative pressure to achieve an effective FRC
- Has low laryngeal tone to maintain PEEP by grunting
- Fluid clearance from lung depends on gestational age of baby because of immature amiloride sensitive Na channel
- Lack of fat laden superficial fascia in the neck → which stabilize the airway
- Not able to mobilize effectively the genioglossus muscle that normally stabilizes the pharynx

- Insufficient numbers of alveolar channels for collateral ventilation
- Chest wall is soft and horizontal ribs and flatter which reduces the potential for lung expansion
- During REM sleep, intercostal muscle activity may be lost
- PDA predisposing to pulmonary edema
- Deficient surfactant.

Effects of CPAP in the infant with respiratory distress:

- Reduces upper airway occlusion by decreasing upper airway resistance and increasing the pharyngeal cross sectional area
- Increases the FRC
- Reduces inspiratory resistance by dilating the airways. This permits a larger tidal volume for a given pressure, so reducing the work of breathing
- Increases the compliance and tidal volume of stiff lungs with a low FRC by stabilizing the chest wall and counteracting the paradoxical movements
- Regularizes and slows the respiratory rate
- Reduces the incidence of apnea
- Increases the mean airway pressure and improves ventilation perfusion mismatch
- Conserves surfactant on the alveolar surface
- Diminishes alveolar edema

Continuous Positive Air Pressure Delivery

CPAP Interfaces⁴

Nasal CPAP devices (Fig. 1) fall into four groups:

1. A long nasopharyngeal tube
2. A single nasal prong
3. Nose masks
4. Short binasal prongs.

Pooled analysis of randomized trials demonstrated that short binasal prongs are more effective at preventing reintubation than single nasal prongs.⁵

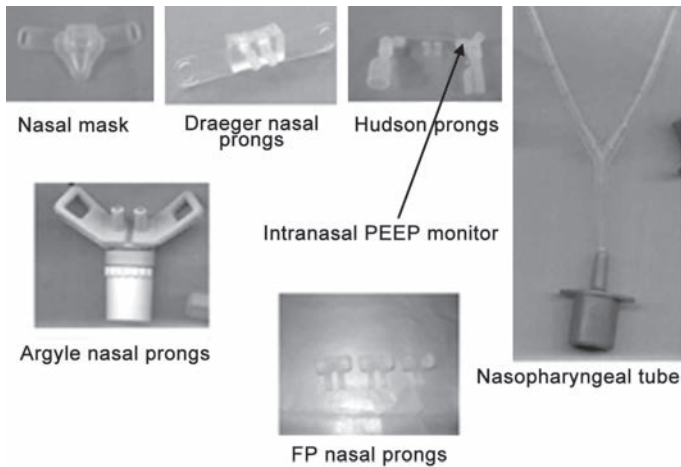

Fig. 1: Different types of nasal interfaces

The way CPAP pressure is generated is distinct from the interface device. There are four techniques for generating nasal CPAP.⁴

1. **Bubble CPAP:** With this technique gas flows past the nasal device and the pressure is generated in the circuit by placing the distal limb of the CPAP circuit under a known depth of water. Gas flow is increased until continuous bubbling is achieved (Fig. 2).
2. **Ventilator CPAP:** The ventilator PEEP (end-expiratory pressure) valve controls the CPAP delivered.
3. **Variable flow nCPAP devices:** These devices have an integrated nasal interface and pressure generator. They use a higher gas flow than other devices and pressure is generated by increased resistance as the gas leaves the nasal device. The pressure is determined by altering the flow of gas into the device (Fig. 3).
4. **High flow nasal cannulae:** High flow cannulae deliver gas flows >2 L/ min into the nostrils through small prongs which are loose in the nostrils. Low flow cannulae are used to deliver supplemental oxygen whereas high flow cannulae are used because it is thought that they provide some CPAP.⁶

Fig. 2: Bubble nCPAP

Fig. 3: Variable flow/fluidic flip

Problems of nCPAP⁷

1. **Leak at the nose and mouth:** It has been reported that the pharyngeal pressure drops markedly when the CPAP supported infant opens his mouth. The use of chin strap or pacifier is recommended to reduce mouth leak for effective CPAP support. However, it should not be so tight as to prevent the infant from yawning or crying but tight enough to prevent leaking at rest.
2. **Nasal trauma:** It is mostly caused by incorrect positioning of the prongs. To prevent injury the nasal device must not be pushed up against the columella. Injury can also occur inside the nose and erode the nasal septum if the prongs are not positioned straight into the nostrils.
3. **Gastric distention:** Gastric distention is common in the CPAP supported infant (CPAP belly syndrome). Frequent decompression of the stomach with an orogastric tube is necessary to promote comfort, preventing the distended stomach from splinting the diaphragm and compromising respiration.

How to Prevent Nasal Septal Injury?

Nasal septal injury is absolutely preventable by checking following things:

- Snugly fitting nasal prongs
- Secure caps
- Light weight interface
- Correct positioning and attachment of corrugated tubing (bubble)
- Velcro moustache (Hudson prong, bubble CPAP)
- Careful, frequent observation: give rest
- Careful positioning of the infant.

Indications for nCPAP⁴

- *Delivery room nCPAP:* The data from animal studies suggest that providing positive end-expiratory pressure (PEEP) during resuscitation reduces the alveolar-arterial oxygen gradient proportional to the level of PEEP applied, lowers indicators of acute lung injury, improves alveolar surfactant pool size, and improves oxygenation and ventilation/perfusion matching. Many studies suggested that treating very preterm infants with nCPAP in the delivery room could reduce the intubation rate and incidence of BPD without increasing mortality or morbidity.
- *Respiratory distress syndrome*
- *Prophylactic CPAP for very preterm:* CPAP is a noninvasive method with benefits in the treatment of the respiratory distress in preterm newborn of 28 to 32 gestational weeks. Using early CPAP may reduce necessity for surfactant, mechanical ventilation and BPD.
- *Postextubation:* A systematic review concludes nCPAP provided immediately after extubation to preterm infants reduced the rate of respiratory failure without clinically important side effects.

CURRENT PERSPECTIVE OF USE OF CPAP

CPAP was first reported in 1971 for supporting breathing of preterm neonates by Gregory GA.⁸ In the seventies, Dr. Jen-Tien Wung⁹ at the Columbian Presbyterian Medical Center, New York developed the bubble CPAP system using short nasal prongs. Columbia University, where the predominant mode of respiratory support was the use of nasal CPAP, had the lowest incidence of CLD without any significant difference in mortality. This renewed the interest of neonatologists in CPAP. The recent experience from Columbia University has been presented in more depth by Ammari et al,¹⁰ who reviewed the courses of 261 infants <1250 gram and reported their outcomes at 72 h of age based on the initial respiratory support modality. After resuscitation and stabilization at delivery, the bubble CPAP is routinely used as initial treatment in breathing very-low-birth-weight infants with RDS within 5 to 10 minutes of birth. Notably, only 51 percent of the infants who were CPAP failures and 53 percent of infants ventilated from birth received surfactant. Withholding surfactant treatment in such cases might have contributed to both

mortality and morbidity and cannot be evaluated because of incomplete patient details. In COIN trial, Colin J Morley¹¹ randomly assigned 610 infants who were born at 25 to 28 weeks' gestation to CPAP or intubation and ventilation at 5 minutes after birth. At 28 days, there was a lower risk of death or need for oxygen therapy in the CPAP group than in the intubation group (OR 0.63; 95% CI, 0.46 to 0.88; P = 0.006). There was little difference in overall mortality. The incidence of pneumothorax was 9 percent in the CPAP group, as compared with 3 percent in the intubation group (P<0.001). There were no other serious adverse events. The CPAP group had fewer days of ventilation.

NASAL INTERMITTENT POSITIVE PRESSURE VENTILATION⁴

Any mode of assisted ventilation that delivers positive pressure throughout the respiratory cycle with additional phasic increases in airway pressure, without the presence of an endotracheal tube. These additional phasic increases in airway pressure either synchronized or non-synchronized depending on the delivery system used. Nasal intermittent positive pressure ventilation (NIPPV) provides the benefits of CPAP with the addition of positive pressure breaths.

Terminology Used

- SNIPPV—synchronized nasal intermittent positive pressure ventilation
- NP-SIMV—nasopharyngeal synchronized intermittent mandatory ventilation
- N-SIMV—nasal synchronized intermittent mandatory ventilation
- N-SIPPV—nasal synchronized intermittent positive pressure ventilation
- N-BiPAP—nasal bilevel positive airway pressure
- NIMV—nasal intermittent mandatory ventilation
- NI-PSV—noninvasive pressure support ventilation

How does NIPPV Work?

The mechanism of action of NIPPV remains uncertain. It is unclear whether mechanical inflations during NIPPV are transmitted to the lungs. Moretti showed that some synchronized breaths were transmitted, but asynchronous breaths were not.

Delivery of NIPPV

Devices to generate NIPPV: Conventilators can be used to deliver nonsynchronized NIMV. The only specialized devices which attempt to provide synchronized NIPPV are the Infant Flow SiPAP and infant flow advance — IFDa (Viasys Healthcare, Conshohocken, PA, USA).

Nasal interface: Mask or prong.

How to start NIMV: Ventilator settings:

- No studies have investigated how different settings influence the effectiveness of NIPPV
- In published studies PEEP has ranged from 3 to 6 cm H₂O
- Range of peak pressures during NIPPV including the same PIP as pre-extubation, 2 to 4 cm H₂O higher than pre-extubation PIP 'to see the chest rise' or specific target pressures (16–20 cm H₂O)

However, the delivered pressure may be lower than the set pressure due to leak at the nose and mouth.

Indications

- RDS as a primary treatment
- Apnea of prematurity and
- Postextubation.

Criteria to discontinue NIMV

- Blood gas: If pH <7.2 and PCO₂ >65 mm
- Inability to improve gas exchange or increased work of breathing
- Hemodynamic instability.

SYNCHRONIZATION

Synchronizing NIPPV inflations with an infant's own breaths is theoretically advantageous. Flow sensors are not used because of large and variable leaks at the nose. Nonsynchronized NIPPV may deliver high pressure during spontaneous expiration, increasing the risk of raised upper airway pressure and pneumothorax. No trials have compared synchronized with nonsynchronized NIPPV, or examined the accuracy of synchronization devices in NIPPV.

NIPPV augments CPAP by superimposing ventilator inflations on nasal CPAP. Reviews of randomized controlled trials of NIPPV versus nasal CPAP show that NIPPV is more effective in preventing failure of extubation and may be useful in preterm infants with apnea.¹² No studies have described the use of NIPPV as first line therapy for early respiratory distress.

Complications of NIPPV

- Nasal trauma
- Gastric distention
- Pneumothorax.

INTRODUCTION

Neonatal jaundice or hyperbilirubinemia during the neonatal period is one of the most common clinical condition requiring evaluation and treatment during the first few weeks after birth. It is also one of the most common reason for readmission during the first few weeks after birth and accounts for considerable health care expenditures worldwide.^{1,2} Neonatal jaundice may cause kernicterus or chronic postkernicteric bilirubin encephalopathy (CPKE), a severe neurologically debilitating condition.³ CPKE is largely a preventable condition and therefore it is essential to monitor neonates for jaundice and implement appropriate therapy in a timely manner.⁴ In developed countries, the incidence of severe jaundice (total serum bilirubin [TSB] ≥ 20 mg/dL) and associated bilirubin encephalopathy is low, however, in developing countries such as India and Africa, this preventable disease still occurs in epidemic proportion.⁵⁻¹⁰

BILIRUBIN METABOLISM

To better understand the etiology and pathophysiology of neonatal jaundice, it is essential to first understand bilirubin metabolism. Bilirubin is produced in a two-step process involving catabolism of heme which is present in hemoglobin, myoglobin, and other hemoproteins such as cytochromes and catalase.^{11,12} Although hemoglobin is the primary source of bilirubin, other sources may account up to 20 percent of bilirubin load, specifically in premature infants. In the first step of the 2-step process of catabolism, heme undergoes series of oxidation and reduction to be first broken down by microsomal heme oxygenase to biliverdin and simultaneously releasing carbon monoxide and ferrous iron. The first step is a rate limiting step. Moreover, heme-oxygenase enzyme is inducible not only by its substrate but also by oxidative stress strongly

indicating its putative role in antioxidant defense mechanism. Bilirubin is a known potent antioxidant and may have important role in prevention of free oxygen radical injuries commonly seen among premature infants.¹³ In the second step of heme catabolism which occurs in cytosol, biliverdin is reduced to bilirubin by biliverdin reductase. In this two step catabolic process, an equimolar concentration of carbon monoxide is produced and excreted via lungs and therefore end tidal carbon monoxide or carboxyhemoglobin concentration (corrected for ambient carbon monoxide) can be used as an index measure of bilirubin production.¹⁴ The bilirubin production in neonates is about 2 to 3 times greater than that of adults because of shortened erythrocyte life span (~80 days compared to ~120 days in the adult), increased turnover of hemoproteins, and cessation of hematopoiesis at birth leading to increased heme degradation.¹⁵ Hemolytic disorders such as G6PD deficiency, ABO incompatibility, Rhesus incompatibility, and hereditary spherocytosis are disorders associated with excessive bilirubin production.

The native form of bilirubin produced as a result of heme catabolism is an unconjugated bilirubin. Its bichromophoric tetrapyrrole structure, two dipyrroles separated by a saturated linkage, leads to its yellow color.¹⁶ The native bilirubin in its usual conformation (IX- α , Z,Z isomer) has its two rigid dipyrrole units internally hydrogen bonded to each other such that no polar (or ionizable) groups are exposed making it quite nonpolar and insoluble in water at normal pH.¹⁶ The unconjugated bilirubin is a lipid-soluble molecule that readily crosses biomembranes, including blood-brain barrier and neuronal cell membranes. The native bilirubin has been shown to be neurotoxic in both *in vivo* and *in vitro* studies.^{17,18}

The nonpolar unconjugated bilirubin released into the blood circulation from the reticuloendothelial system binds immediately to albumin which appears a protective

mechanism as bilirubin bound to albumin does not cross intact blood-brain barrier. The emerging literature suggests that free or unbound unconjugated bilirubin and not bilirubin bound to albumin crosses intact blood brain barrier and causes neurotoxicity.¹⁸⁻²³ There appears to be two major bilirubin binding sites on albumin and on an average each gram of albumin binds 8 mg/dl of unconjugated bilirubin in term neonates. In premature infants, the albumin concentration, bilirubin binding capacity, and bilirubin binding affinity (or strength of binding) is lower compared to term infants, increasing the risk of bilirubin toxicity.²⁴ The bilirubin bound to albumin can be displaced by strong displacers such as sulfa drugs, ibuprofen, ceftriaxone, and therefore medications known to strongly displace bilirubin are not recommended in the presence of unconjugated hyperbilirubinemia.^{17,25} In addition, in premature infants, several clinical factors such as intravenous fat emulsions, steroid usage, infection, etc. can be associated with elevated free fatty acid concentration, a known endogenous bilirubin displacer that has been shown to compete for bilirubin albumin binding sites. Therefore, to prevent a displacing effect, intravenous fat emulsion intake is limited in the presence of unconjugated hyperbilirubinemia. Recent studies suggest that the displacing effect of intravenous fat emulsion is gestational age dependent and is not seen in premature infants >30 weeks gestational age.^{26,27}

Unconjugated bilirubin bound to albumin is transported to liver where bilirubin dissociates from albumin and enters the hepatic cell by a process of carrier mediated diffusion. The carrier mediated diffusion into the hepatic cell and subsequent intracellular transport to endoplasmic reticulum is facilitated by two carrier proteins, Y and Z proteins (or organic anion transporters). In the endoplasmic reticulum of the hepatocytes, uridine diphosphoglucuronate glucuronosyl transferase (UGT) catalyzes transfer of one glucuronic acid molecule from the activated uridine diphosphoglucuronic acid (UDPGA) to bilirubin to form bilirubin monoglucuronide. Although bilirubin monoglucuronide is water soluble and can be easily excreted, additional conjugation occurs by the transfer of one molecule of glucuronic acid from one molecule of bilirubin monoglucuronide to another, resulting in the formation of bilirubin diglucuronides. This process is catalyzed with the help of transglucuronidase present in the canalicular border of the hepatic cell membrane. The conjugation process results in alteration of bilirubin molecule such that it prevents intramolecular hydrogen bonding and renders it water soluble. The maturational deficient activity of hepatic UGT during the first few hours to days after birth may contribute to unconjugated hyperbilirubinemia, specifically in premature infants. Hypothyroidism and inherited disorders such as Crigler-Najjar syndrome type 2 are associated with decreased activity of conjugating enzyme while Crigler-Najjar

syndrome type 1 is associated with absent hepatic UGT activity.

The water soluble conjugated bilirubin is then excreted from the hepatocyte into the biliary tree. The excretion process appears to be energy dependent as it occurs against a concentration gradient because bilirubin bile concentration is several folds greater in biliary tract than in hepatocytes. In the presence of hepatic cell injury or bilirubin obstruction, excretion is adversely affected leading to conjugated hyperbilirubinemia.

In the intestine, conjugated bilirubin can be deconjugated to unconjugated bilirubin in the presence of an alkali media or with the help of an enzyme beta-glucuronidase that is abundantly present in the intestinal mucosa, specifically in premature infants. The deconjugated bilirubin because of lipid solubility can then be reabsorbed (enterohepatic circulation) increasing the bilirubin load in the circulation. The enterohepatic circulation may account up to 25 percent of bilirubin load or TSB in the circulation, specifically in premature infants. The rest of bilirubin is converted to stercobilin by bacterial flora in the intestine and excreted in feces. Enteral feeding favors establishment of bacterial flora in the gut and helps conversion to stercobilin. Therefore, infants not receiving enteral feeding may have increased enterohepatic circulation.

It is evident from the understanding of bilirubin metabolism that bilirubin exists in four different forms in the blood:

- Unconjugated bilirubin not bound to albumin (also called free unconjugated bilirubin)
- Unconjugated bilirubin bound to albumin
- Free conjugated bilirubin
- Conjugated bilirubin bound to albumin also called 'δ' bilirubin. The free unconjugated bilirubin is present in extremely small amount under normal conditions. Hyperbilirubinemia is classified as either unconjugated hyperbilirubinemia or conjugated hyperbilirubinemia based on the relative proportion of bilirubin forms. The biochemical assays commonly used to measure and differentiate conjugate and unconjugate bilirubin concentration are based on van den Bergh reaction using diazo reagents. The direct reaction with diazo reagent reflects free conjugated bilirubin and not the 'δ' bilirubin, while indirect reaction with diazo reagent reflects unconjugated bilirubin (bound or free). Unconjugated hyperbilirubinemia is defined as an indirect-serum bilirubin concentration of ≥ 2 mg/dl. Conjugated hyperbilirubinemia is defined as direct serum bilirubin concentration ≥ 2 mg/dL and more than 20 percent of TSB concentration. The etiology and pathogenesis of conjugated or direct hyperbilirubinemia during neonatal period is much different from unconjugated hyperbilirubinemia and is beyond the scope of this chapter.

PATHOLOGY OF BILIRUBIN-INDUCED NEUROTOXICITY

Bilirubin has specific predilection for specific areas of brain that includes various cranial nerve nuclei particularly the cochlear nuclei, vestibular nuclei and oculomotor nuclei; various brainstem nuclei, particularly the reticular formation of the pons; the inferior olivary nuclei; the cerebellar nuclei, particularly the dentate; the basal ganglia, specifically, globus pallidus and subthalamus; the hippocampus, specifically, the sectors H2-3; and cerebellar vermis.¹⁷ Current literature suggests that auditory system is the most sensitive system to overt bilirubin induced neurotoxicity.¹⁷ Recent studies have shown that unconjugated bilirubin induced toxicity leads to neuronal cell death by both apoptosis and necrosis.^{28,29} Bilirubin neurotoxicity has been associated with long-lasting reduced neuritic outgrowth.²⁸ Unconjugated bilirubin has also been shown to affect myelination process by damaging oligodendrocytes.^{29,30}

CLINICAL MANIFESTATION

Neonatal jaundice is an extremely common neonatal problem with ~60 percent of late preterm and term infants have yellowish discoloration of skin, a clinical manifestation associated with transient elevations of serum bilirubin. Very premature infants (less than 32 weeks gestational age) may not manifest yellowish discoloration and usually need bilirubin levels to diagnose neonatal jaundice or hyperbilirubinemia. Overall, the incidence of hyperbilirubinemia defined as TSB ≥ 2 mg/dl is higher among premature infants compared to term infants with most premature infants developing some degree of hyperbilirubinemia. In developed countries, because of close monitoring and timely evaluation, only 5 to 15 percent of term neonates develop TSB levels greater than 12.9 mg/dl and even fewer develop severe jaundice (TSB levels ≥ 20 mg/dl).³¹ The true incidence of severe jaundice in developing countries is unknown but is thought to be much higher than that in developed countries.⁶

During fetal life, unconjugated bilirubin produced in fetus is easily transferred across placenta into maternal circulation and therefore neonates are rarely born with clinical manifestation of jaundice. The yellow discoloration of the skin and sclera is not usually seen until the TSB is >5 mg/dl. It is first seen on the face and then spreads down the body in a cephalocaudal progression. In order to appreciate clinical jaundice, examination should be done in the presence of adequate light and the skin should be blanched with a dermal pressure. Jaundice may be difficult to detect in darker-skinned infants and moreover estimation of TSB using inspection of anatomic progression of jaundice is often subjective and unreliable. Unconjugated bilirubin in the skin appears yellow or orange, whereas, conjugated bilirubin appears more greenish.

In term neonates, unconjugated hyperbilirubinemia typically peaks on day 2 to 5 of life at ~ 10 to 12 mg/dl among Asians, and ~ 5 to 6 mg/dl among Caucasians and Africans. The hyperbilirubinemia then decrease over the next few weeks to levels less than 2 mg/dl. This mild degree of hyperbilirubinemia is explained by physiological imbalance between bilirubin production and excretion during the first few days after birth and is considered physiological in the absence of known causes of pathological jaundice. In premature infants, physiological jaundice is more severe and peaks on day 5 to 7 compared to term infants. This is mainly explained by delay in maturation of hepatic conjugating enzymes in premature infants.

Additional clinical manifestations that may be present in term and late preterm neonates with jaundice include signs of dehydration, hemolysis, and/or acute bilirubin encephalopathy. The signs of dehydration secondary to insufficient enteral intake include lethargy, significant weight loss ($>10\%$ of birth weight), dry mucous membranes, decreased urine output, poor capillary refill, sunken eyes and fontanelle and poor skin turgor. Signs of hemolysis include pallor and enlarged spleen and liver.

All late preterm and term infants with moderate and severe neonatal jaundice should be evaluated for signs of acute bilirubin encephalopathy. In the early phase, infants manifest lethargy, hypotonia, and poor suck. In the intermediate phase, infants display high-pitched cry, irritability, and hypertonia (retrocollis-opisthotonos) alternating with drowsiness and hypotonia. During this phase, they may also develop a fever often confusing with a possible diagnosis of sepsis. Infants who reach the late phase may have increased retrocollis-opisthotonos, cessation of feeding, bicycling movements, inconsolable irritability and crying, seizures and coma. Some of these infants who display the late phase of acute bilirubin encephalopathy often die but majority who survive are likely to progress and develop CPKE. The bilirubin-induced neurological dysfunction (BIND) score has been proposed to monitor neurological manifestation of infants with acute bilirubin encephalopathy. BIND score may be a prognostic indicator for later CPKE.³² In premature infants, there are usually no specific clinical manifestations of acute bilirubin encephalopathy. Recent literature suggests that apnea may be the primary manifestation of acute bilirubin encephalopathy in premature infants.²¹

The manifestation of CPKE may take several years to develop and therefore infants with severe jaundice (TSB ≥ 20 mg/dl or those meeting American academy of pediatrics (AAP) criteria for exchange transfusion) should be closely followed and monitored at least during the first 5 years.^{17,33} The signs of CPKE include high frequency sensorineural hearing loss, auditory neuropathy spectrum disorder, upward gaze palsy, choreoathetoid palsy, and dental enamel hypoplasia.¹⁷ Emerging evidence suggests that sensorineural hearing loss and/or auditory

neuropathy spectrum disorder may be the sole manifestation of CPKE in premature infants.¹⁷ Auditory neuropathy spectrum disorder is defined as abnormal auditory neural function in the presence of normal outer hair cell function.^{17,34} Although emerging data suggests that neonatal jaundice may be associated with autism, further well defined studies are required to corroborate this association.³⁵

EVALUATIONS

All newborn infants with clinical jaundice should have TSB concentration measured and plotted on AAP nomogram for need of therapy or to predict probability of developing severe hyperbilirubinemia.³³ The AAP recommends interpretation of TSB levels in terms of the infant's age in hours and not in days. In other words, consider a scenario when TSB levels are measured on day 2 at two separate time points, 24.1 hours and 47.9 hours. A TSB level of 8 mg/dl at 24.1 hours is concerning and warrants further evaluation and a close follow-up, while the same level at 47.9 hours is less concerning. Further laboratory evaluation depends on the magnitude of hyperbilirubinemia. If the TSB concentration is above the 95th percentile for age or is rapidly rising and crossing percentiles, hemolytic jaundice should be ruled out using tests such as Coomb test, blood groups of infant and mother, peripheral smear for abnormal cells, reticulocyte count, and serial hematocrit. The rate of rise in TSB of >0.5 mg/hour in late preterm and term neonates and failure to respond to intensive phototherapy irrespective of age are also indicative of hemolytic jaundice. A thorough history and examination is also warranted as it may uncover a likely cause of jaundice. Several clinical factors have been associated with severe jaundice including breast milk feeding, ABO incompatibility, G6PD deficiency, East Asian ethnicity (China, Japan, Korea), clinical jaundice observed in the first 24 hours of life, cephalhematoma or significant skin bruising, history of previous sibling treated with phototherapy, late preterm infants, and male gender.³³ Some of these risk factors are further described below. Recent evidence suggests that combining risk factors with pre-discharge TSB or transcutaneous bilirubin concentration improves prediction of severe jaundice.^{36,37}

BREAST MILK AND BREAST FEEDING JAUNDICE

There is a strong association between breastfeeding and an increased incidence of neonatal hyperbilirubinemia.³⁸⁻⁴¹ The jaundice associated with breastfeeding during the first postnatal week has been referred to as breastfeeding jaundice. This occurs primarily because of difficulties in lactation resulting in decreased milk intake with fewer calories. The resultant decreased caloric intake or starvation along with delayed meconium passage increases enterohepatic circulation with secondary increase in bilirubin load. This

is usually seen with primigravida mothers, mothers who have delivered via cesarean section, and with late preterm infants. A timely counseling by a lactation consultant or a physician encouraging mothers for frequent breastfeeding (8 to 12 times per day) may prevent breastfeeding jaundice.⁴² The jaundice associated with human milk feeding that occurs beyond the first postnatal week is referred to as breast milk jaundice although there is considerable overlap between the two entities with breastfeeding jaundice often leading to breast milk jaundice. Breast milk associated jaundice has been associated with acute bilirubin encephalopathy and CPKE.⁴³ Animal studies suggest that milk contains beta-glucuronidase which can deconjugate bilirubin in the intestine facilitating enterohepatic circulation. Recent studies suggest that genetic polymorphism in UGT-1A1 or organic anion transporter genes also predispose infants who are receiving human milk to have prolonged and severe unconjugated hyperbilirubinemia.⁴⁴ Breastfeeding should be continued unless the TSB is ≥ 20 mg/dl. Even in such cases, only brief discontinuation of breastfeeding (~24 hours) is recommended. The bilirubin level should decrease with discontinuation of breast feeding. As breast milk feeding is resumed, TSB level will transiently increase by 1 to 3 mg/dl before gradually decreasing over several days despite continuation of breast milk feeding. This therapeutic response is highly indicative of breast milk jaundice.

Male Gender

Although the reasons are unknown, several studies have reported increased risk of severe jaundice in male neonates compared to female neonates.^{33,45} The higher prevalence of Gilbert syndrome and G6PD deficiency among males partly explain the increased incidence of severe jaundice in male neonates. There also appears to be increased susceptibility to bilirubin-induced injury in male neonates based on available literature.⁴⁶

Late Preterm Infant (34 to 37 Weeks Gestational Age)

Neonatal hyperbilirubinemia is more common and pronounced in late preterm infants compared to term infants.⁴⁶ There is a delay in postnatal maturation in hepatic bilirubin conjugation capacity in late preterm infants which may partly explain a higher incidence of severe jaundice in late preterm infants compared to term infants.⁴⁷ Moreover, late preterm neonates who are breastfed are also prone to lactation failure because of immaturity in sucking and swallowing and may therefore contribute to the genesis of severe jaundice in this population.⁴⁸ More importantly, the signs of bilirubin encephalopathy appear at an earlier postnatal age in late preterm infants compared to term infants suggesting that late preterm infants are more vulnerable to bilirubin-induced neurotoxicity.⁴³

ABO Hemolytic Disease

In developed countries, ABO incompatibility is the most common cause of hemolytic disease in neonates. In parts of developing countries where anti-D immunoglobulin G (RhoGAM) is routinely given to mother to prevent rhesus sensitization, ABO incompatibility is rapidly becoming the most common cause of hemolytic disease. ABO hemolytic disease has a variable clinical presentation with most presenting with rapidly progressive jaundice during the first couple of days after birth. However, compared to Rh D incompatibility where 100 percent of infants have positive direct antiglobulin test (Coombs) test, only 20 to 30 percent of infants with history of ABO incompatibility have positive direct Coombs test. Of these with positive direct coombs test, only 20 percent develop moderate to severe jaundice because of neutralizing of maternal IgG antibody by placental antigens and weak nature of A or B antibody.⁴⁹ A positive direct Coombs test indicate that anti-A or anti-B antibodies are attached to red cells but do not indicate hemolysis. A corroborative evidence of hemolysis is needed to diagnose ABO hemolytic jaundice. In term, infants with ABO incompatibility, other causes of hemolysis should be considered in the absence of positive Coombs test, however it is also important to remember that Coombs test has significant false negative rate in ABO incompatible neonates with hemolysis.^{50,51} More recently, co-existence of Gilbert syndrome (genetic polymorphism in UGT1A1) with coombs negative ABO incompatibility was shown to increase the risk of severe hyperbilirubinemia.⁵²

Glucose-6-phosphate Dehydrogenase (G6PD) Deficiency

G6PD deficiency is the most common and clinically significant red cell enzyme defect, affecting as many as 5 million newborns worldwide each year.^{53,54} G6PD deficiency is an X-linked condition primarily affecting hemizygous males and homozygous females but may affect heterozygous females (by way of nonrandom X chromosome inactivation). Several trigger factors such as illness, sulfa drugs, fava beans, naphthalene in moth balls, etc. are known to cause acute hemolysis in G6PD deficient infants. Besides hemolysis, G6PD deficient infants may have genetic polymorphisms involving UGT1A1 or organic anion transporter gene with impaired ability to conjugate bilirubin and hepatic uptake, respectively.⁵³ Infants with unexplained severe jaundice should be investigated for G6PD deficiency. It is important to recognize that G6PD assay may be false negative soon after the episode of hemolysis and should be repeated few weeks after hemolysis to rule out G6PD deficiency.

TREATMENT OF NEONATAL JAUNDICE

The AAP subcommittee on hyperbilirubinemia recommends phototherapy or exchange transfusion using hour-specific TSB levels for three separate groups of neonates defined based on gestational age and presence of risk factors: (1) Infants at lower risk (at least 38 weeks gestation and well); (2) Infants at medium risk (at least 38 weeks gestation with risk factors [defined as isoimmune hemolytic disease, G6PD deficiency, asphyxia, significant lethargy, temperature instability, acidosis, or albumin less than 3.0 g/dl] or 35^{0/7} to 37^{6/7} weeks gestation and well); (3) Infants at higher risk (35^{0/7} to 37^{6/7} weeks gestation with risk factors).³³ Each neonatal or pediatric unit involved in the care of infants with moderate to severe jaundice should have easy access to bilirubin graphs published by the AAP.³³ Alternatively, one can use instruments such as BiliTool (access at www.bilitool.org) which can be easily downloaded. Bilirubin:Albumin ratios should be used as an additional risk factor but not in lieu of the TSB in determining the need for exchange transfusion.³³ There are no guidelines for infants born between 34^{0/7} and 34^{6/7} weeks gestation because of lack of evidence. Secondly, the threshold level of TSB remains the same beyond the fourth day after birth. Thirdly, infants born between 37^{0/7} and 37^{6/7} weeks gestation (although term infants) are managed as late preterm regarding treatment with phototherapy or exchange transfusion.

Phototherapy is the mainstay of treatment for moderate to severe unconjugated hyperbilirubinemia.⁵⁵ Phototherapy induces geometric and structural isomerism of native bilirubin structure resulting in products that can be easily excreted in the bile or in the urine without further conjugation.⁵⁵ Several factors affect the efficacy of phototherapy including infant's distance from the light source, surface area exposed, type of phototherapy, and dose of phototherapy. At wavelengths between 425 and 490 nm (blue green spectrum), light penetrates the skin well and is absorbed maximally by serum bilirubin. Intensive phototherapy (irradiance of at least 30 mcW/cm²/nm) delivered to as much of the infant's surface area as possible is recommended by the AAP for the management of infants with severe jaundice.³³ For infants with TSB level at which exchange transfusion criteria is recommended, intensive therapy should be started immediately while preparations for exchange transfusion are made. When intensive phototherapy is applied, ~ 30 percent decrease in TSB concentration is expected within the first 24 hours, with the most significant decrease occurring in the first 4 to 6 hours. If the TSB does not decrease with intensive phototherapy within 4 hours after initiation, then exchange transfusion should be performed immediately. For infants

demonstrating signs of acute bilirubin encephalopathy or infants with TSB >5 mg/dl above the TSB level at which exchange transfusion is indicated, immediate exchange transfusion is indicated as per AAP guidelines.

Several studies have demonstrated effectiveness of high dose (500 to 1000 mg/kg) intravenous immunoglobulin therapy in decreasing hemolysis associated with Coombs positive hemolytic disease (Rh isoimmunization and ABO incompatibility).^{33,56} The number of infants needed to treat with intravenous immunoglobulin is 3 to prevent one exchange transfusion.⁵⁶ Intravenous immunoglobulin should be given slowly (over at least 2 hours) and can be repeated at 12 hours intervals until the bilirubin level stabilizes.

PREVENTION

Severe neonatal jaundice and its sequelae including acute bilirubin encephalopathy and CPKE are largely preventable. Preventive measures include the use of RhoGAM to prevent rhesus sensitization; universal screening for jaundice using serum or transcutaneous bilirubin measurement before newborn discharge to identify at-risk infants; provision of lactation consultant and breast pumps to avoid lactation failure and associated breastfeeding jaundice; parental counseling and education before newborn discharge regarding the need for timely follow-up with a physician for jaundice to prevent severe jaundice and appropriate therapy based on bilirubin thresholds and clinical risk factors as recommended by the AAP to decrease the incidence of severe hyperbilirubinemia and bilirubin encephalopathy.

FOLLOW-UP OF INFANTS WITH SEVERE JAUNDICE

All infants with severe jaundice (TSB \geq 20 mg/dl) or with TSB level at which exchange transfusion is indicated as per AAP guidelines should be followed for abnormal neurodevelopmental outcome during early childhood. These infants should be evaluated for auditory neuropathy spectrum disorder and sensorineural hearing loss using appropriate audiological evaluations.⁵⁷ Infants with severe jaundice should be followed annually for findings of CPKE and BIND during the first 5 years even in the absence of acute bilirubin encephalopathy at the time of severe jaundice.³² Early identification and appropriate intervention may decrease the severity of CPKE.

Approach to Cholestatic Jaundice in Newborn

Ajay Kumar Jain

BACKGROUND

Cholestatic jaundice is a serious pathological process indicating hepatobiliary dysfunction. It results from an alteration in bile flow and/or its excretion. Early detection and prompt intervention are critical. It is of paramount importance to differentiate cholestatic jaundice from physiologic jaundice of the newborn. Physiologic jaundice usually resolves by day 14 of life and is classically unconjugated hyperbilirubinemia. By two weeks of age—a small percent of newborns are still jaundiced.^{1,2} Among these a smaller percent would have biliary atresia requiring timely diagnosis and treatment, with a majority having benign breast milk jaundice. It is recommended that any child noted to be jaundiced at 2 weeks of age should be evaluated for cholestasis.³

Retention of bile components in the serum result in the biochemical features of cholestasis. Though the pattern and severity of these serum markers (Gamma glutamyl transferase, bilirubin, bile acids, liver panel, lipid profile, etc.) vary with the etiology, an elevated conjugated bilirubin is the hallmark in patients presenting with neonatal cholestasis. Cholestatic processes in the newborn can result from a myriad of pathologies as described in Table 1.

Neonatal conjugated hyperbilirubinemia is defined by a serum conjugated bilirubin concentration above 1.0 mg/dL (17.1 micromol/L) if the total serum bilirubin is <5.0 mg/dL (85.5 micromol/L) or above 20 percent of the total serum bilirubin if the total serum bilirubin is >5.0 mg/dL (85.5 micromol/L).³ Approximately 1 in every 2,500 infants have cholestatic jaundice of varying severity.^{4,5}

INITIAL EVALUATION

Since this chapter focuses on our approach to a patient with cholestatic jaundice, the authors, rather than focusing

on the individual disorders would take a holistic approach leading to a stepwise evaluation of such patients. Of paramount importance is a detailed history and examination.

History

A comprehensive history goes a long way in patient evaluation and leading to clues regarding the etiology of conjugated hyperbilirubinemia. It is important to address some of the following specific aspects of the history as detailed below:

1. *Infections:* Conjugated hyperbilirubinemia has been well described in association with bacterial infections. This likely result from the deleterious effects of bacterial endotoxin(s) on hepatic nuclear factors and bile formation.^{6,7} In clinically asymptomatic infants, conjugated hyperbilirubinemia, especially if it occurs after 8 days of life may result from urinary tract infection.⁸ Jaundice culminating from an underlying infectious process tends to resolve once the infection has been treated. Thus, it is vital to obtain a history of maternal or infantile fever, rashes or evidence of process indicating an infectious etiology.
2. *Stools:* Pale or clay colored stools reported by parents, though not diagnostic, raise the suspicion for cholestasis and is an important component of patient history. However, it is well reported in literature for infants with biliary atresia and other cholestatic diseases to have a variable stool color and be grossly pigmented at presentation.^{3,9} Persistent pale stools have been reported to have high specificity in clinical studies indicating liver disease. Parents are not always reliable historians for stool color even when asked specifically “What color is your baby’s stool?”.^{9,10} Modest improvement was shown in studies where a score card showing normal and abnormal stool color was presented to families.¹¹ The authors recommend that patterns of

<i>Extrahepatic disorders</i>	Rotor syndrome
Biliary atresia	Dubin-Johnson syndrome
Bile duct stricture/neonatal sclerosing cholangitis	Mitochondrial hepatopathies
Choledochal cyst	Other metabolic defects
Anomalies of the pancreaticoduodenal junction	α 1-Antitrypsin deficiency
Spontaneous perforation of the bile duct	Cystic fibrosis
Inspissated bile	Hypopituitarism
Mass	Hypothyroidism
Intraductular: Stone, rhabdomyosarcoma	Neonatal iron storage disease
Extraductular: Hepatoblastoma, neuroblastoma	Infantile copper overload (Menkes syndrome)
<i>Intrahepatic disorders</i>	Hemophagocytic lymphohistiocytosis
Idiopathic	Arginase deficiency
“Idiopathic” neonatal hepatitis	<i>Toxic</i>
Intrahepatic cholestasis, persistent	Total parenteral nutrition–associated cholestasis
Severe intrahepatic cholestasis with progressive hepatocellular disease	Fetal alcohol syndrome
Alagille syndrome (syndromic paucity of the intrahepatic bile ducts, arteriohepatic dysplasia)	Other drugs (maternal or used in neonatal intensive care)
Nonsyndromic paucity of the intrahepatic bile ducts	<i>Cholestasis associated with infection</i>
Intrahepatic cholestasis, recurrent	Sepsis with possible endotoxemia (urinary tract infection, gastroenteritis)
Benign recurrent intrahepatic cholestasis	Syphilis
Hereditary cholestasis with lymphedema (Aagaard syndrome)	Toxoplasmosis
Anatomic	Listeriosis
Congenital hepatic fibrosis or infantile polycystic disease (liver and kidney)	Congenital viral infections
Caroli disease	Cytomegalovirus
Metabolic or endocrine disorders	Herpes virus (herpes simplex and human herpes virus 6)
Disorders of amino acid metabolism	Cocksackievirus
Tyrosinemia	Echoviruses
Disorders of lipid metabolism	Rubella virus
Cholesterol ester storage disease (Wolman)	Hepatitis B virus
Niemann-Pick disease	Other hepatitis viruses
Gaucher disease	Human immunodeficiency virus (HIV)
Disorders of carbohydrate metabolism	Parvovirus B19
Galactosemia	<i>Chromosomal</i>
Fructosemia	Trisomy 18
Glycogen storage disease type IV	Trisomy 21 (Down syndrome)
Disorders of bile acid metabolism, primary	Donohue syndrome (leprechaunism)
β -Hydroxysteroid δ 5-C27 steroid dehydrogenase/ isomerase	<i>Vascular disorders</i>
δ 5–3-Oxosteroid δ 5 β -reductase (multiple mutations)	Budd-Chiari syndrome
Disorders of bile acid metabolism, secondary	Perinatal asphyxia
Zellweger syndrome (cerebrohepatorenal syndrome)	Multiple hemangiomata
Peroxisomal enzymopathies	Cardiac insufficiency
(Adapted from W Allan Walker, Ronald E Kleinman, Philip M Sherman, Benjamin L Shneider, Ian R Sanderson: Pediatric Gastrointestinal Disease)	<i>Miscellaneous</i>
Disorders of bile acid transport	Congenital disorders of glycosylation
	Shock, hypoperfusion
	Intestinal obstruction
	Neonatal lupus
	ARC syndrome (arthrogryposis, renal tubular dysfunction, and cholestasis)

3. Persistent or intermittent irritability or vomiting may indicate metabolic disease or sepsis. A history of lethargy, seizures or delayed milestone achievement may indicate metabolic disease, hypothyroidism or panhypopituitarism. A family history of early childhood

deaths or jaundice can indicate an inherited disorder like progressive familial intrahepatic cholestasis (PFIC), cystic fibrosis, alpha-1 antitrypsin deficiency, etc.

4. *Parenteral nutrition:* It is important to inquire about the use of parenteral nutrition. Parenteral nutrition has been in use since the 1960s. It has been one of the most promising modalities of nutrition in neonates and older pediatric patients with lost or impaired gut functions. There are over several thousand patients permanently dependent on parenteral nutrition (PN) for survival. In addition, there are several fold higher numbers of patients requiring PN for varying duration during hospital stay or home care. Unfortunately, its use is associated with complications of sepsis and Parenteral Nutrition Associated Liver Disease (PNALD).¹² The clinical spectrum of PNALD includes steatosis, disruption in glucose and lipid metabolism, cholestasis, cholelithiasis, hepatic fibrosis, biliary cirrhosis, development of portal hypertension and liver failure. Among the various postulated mechanisms, a lack of enteral feeding resulting in the disruption of enterohepatic circulation appears to be a major contributor towards PNALD, with its greatest predilection in patients on total parenteral nutrition and no enteral nutrition. Thus both the duration and the percentage of parenteral nutrition versus enteral nutrition being provided to a patient are critical in the development of PNALD.¹³

Physical Examination

General Examination

Assessment of general health including vital signs and anthropometric parameters is essential.³ Infants with metabolic disease or infections may be ill appearing or with poor growth, alternatively patients with biliary atresia are generally healthy other than being jaundiced. Like biliary atresia, patients with Alagille syndrome appear healthy, however, they may have characteristic triangular facies and physical appearances.¹⁴ Fundoscopic examination may give clues to a congenital infection or metabolic diseases as would infants tone, vigor and general symmetry. Skin rashes, jaundice, petechiae or bruising are important to document and cannot be ignored. Abdominal examination is essential to evaluate hepatic or splenic enlargement, contour, consistency. Polysplenia is associated with a subtype of biliary atresia. Hepatosplenomegaly may indicate a storage disorder. The presence of abdominal masses, ascites, prominent veins or umbilical hernia may indicate pathology. Patients with Alagille syndrome have a characteristic cardiac systolic murmur and thus a thorough cardiac exam is of paramount importance.^{15,16}

The detection of cholestasis is dependent largely on the clinical recognition of jaundice, along with subtle clues obtained on history and examination as no screening test is predictive of cholestasis. Though, each of these findings is an imperfect method of detecting cholestasis, it forms the basis for further evaluation.^{17,18}

LABORATORY STUDIES

Blood

To establish cholestasis it is important to obtain conjugated bilirubin levels. It is equally important to determine extent of hepatic dysfunction in an effort to evaluate etiology and further intervention. The authors recommend a complete liver panel to include total and conjugated bilirubin, serum alanine aminotransferase (ALT) and aspartate aminotransferase (AST), serum alkaline phosphatase, albumin level and gamma-glutamyl transpeptidase (GGT). Elevated GGT can indicate bile duct damage and raises concerns for biliary atresia.^{19,20} Such an evaluation in conjunction with transaminases may also help in diagnosing conditions like progressive familial intrahepatic cholestasis (PFIC) as well as neonatal cholestasis. In addition marked serum bile acid elevation is also indicative of PFIC especially with modestly elevated conjugated bilirubin and GGT levels.^{21,22} Though transaminases can help determine hepatic injury they may not accurately define hepatic synthetic abilities. Such evaluation of hepatic biosynthetic capacity may be assessed by prothrombin and partial thromboplastin time (PT, PTT), as they require clotting factors produced by the liver. Serum albumin and glucose concentrations would also similarly help.^{23,24} Elevated blood ammonia may indicate an impaired hepatic ability to clear endogenous substances. A complete blood count, platelet count, blood culture, urine culture and urine analysis may help point to an infectious etiology. Urine reducing substances are known to be elevated in patients with galactosemia provided a lactose containing milk (including breast milk) is being fed.^{25,26} Serum bicarbonate or pH disturbances are indicative of metabolic diseases. Other tests to include are thyroid function test, sweat chloride or mutation analysis for cystic fibrosis, lipid panel (cholesterol elevation seen with Alagille syndrome) and alpha 1 antitrypsin level with Pi typing. Radiological evidence of butterfly vertebrae in a cholestatic infant raises suspicion for Alagille syndrome. Use of specific markers for infective hepatitis like CMV, EBV, including a viral hepatitis panel (Hepatitis A-E) might be a consideration.²⁷⁻²⁹ As the etiological processes resulting in cholestasis are varied and can govern laboratory testing, specific situation may warrant additional testing.

IMAGING STUDIES

Ultrasonography

Abdominal ultrasonography being a noninvasive and a relatively widely available test is commonly used as the initial test. It serves as an effective initial tool to assess the hepatobiliary structures. When correlated with pathologic, surgical, and subsequent clinical examinations, the sensitivity and specificity of a small or absent gallbladder in detecting obstruction is reported at 73 percent and 67 percent, respectively. Indicators for biliary atresia include the inability to visualize the gallbladder and the presence of a triangular cord sign (triangular or band like periportal echogenic density >3 mm in thickness).³⁰⁻³² An ultrasound is however quite helpful in the diagnosis of choledochal cysts. It can also determine echotexture disturbances of the hepatic parenchyma indicative of parenchymal injury.

Hepatobiliary Scintigraphy

A HIDA scan or Hepatobiliary Imino-Diacetic Acid scan involves uptake of technetium-labeled imino-diacetic acid analogs by the hepatocytes and its subsequent excretion into the biliary system. It requires an adequate hepatocellular function and patent biliary tract. An abnormality in this pathway is thus identifiable, helping differentiate biliary atresia from neonatal hepatitis. A 83 percent sensitivity and 33 specificity of scintigraphy has been reported in detecting obstruction. This wide variability is likely due to its institution and operator dependability and variations in use among different centers.^{33,34} A normal uptake but impaired excretion is indicative of biliary atresia, alternatively patients with neonatal hepatitis have appropriate excretion, though delayed uptake due to parenchymal injury.^{3,35,36} Pretreatment for five days with phenobarbital (5 mg/kg/day) has been advocated in some studies as a means to improve the accuracy by enhancing isotope excretion, however due to the potential for delaying a diagnosis, such is not routinely practiced. Scintigraphy helps in determining the patency of the biliary track and differentiating biliary atresia from neonatal hepatitis, however, it should not be used as the sole differentiating criteria.³⁷⁻³⁹ A duodenal aspirate has been used for assessing bile excretion into the duodenum. The test is based on the evaluation of the duodenal aspirate for bilirubin. At a 91 percent sensitivity and 43 percent specificity, with the need for potential fluoroscopic placement of the duodenal tube, this test is not routinely performed.^{3,40,41} However it may have a special importance in situation where other tests are not available or deemed unfeasible.

ADDITIONAL EVALUATION

Cholangiogram

Due to the time sensitivity of biliary atresia management a timely diagnosis is critical. If the above mentioned evaluation is indicative of biliary atresia a percutaneous or intra-operative cholangiogram would be the next logical step. In large studies, it is considered the gold standard in the diagnosis of biliary atresia. A Kasai Surgery (hepatoportoenterostomy) is indicated if contrast is unable to fill the biliary tract or reach the intestine.⁴²⁻⁴⁵

Endoscopic Retrograde Cholangiopancreatography (ERCP)

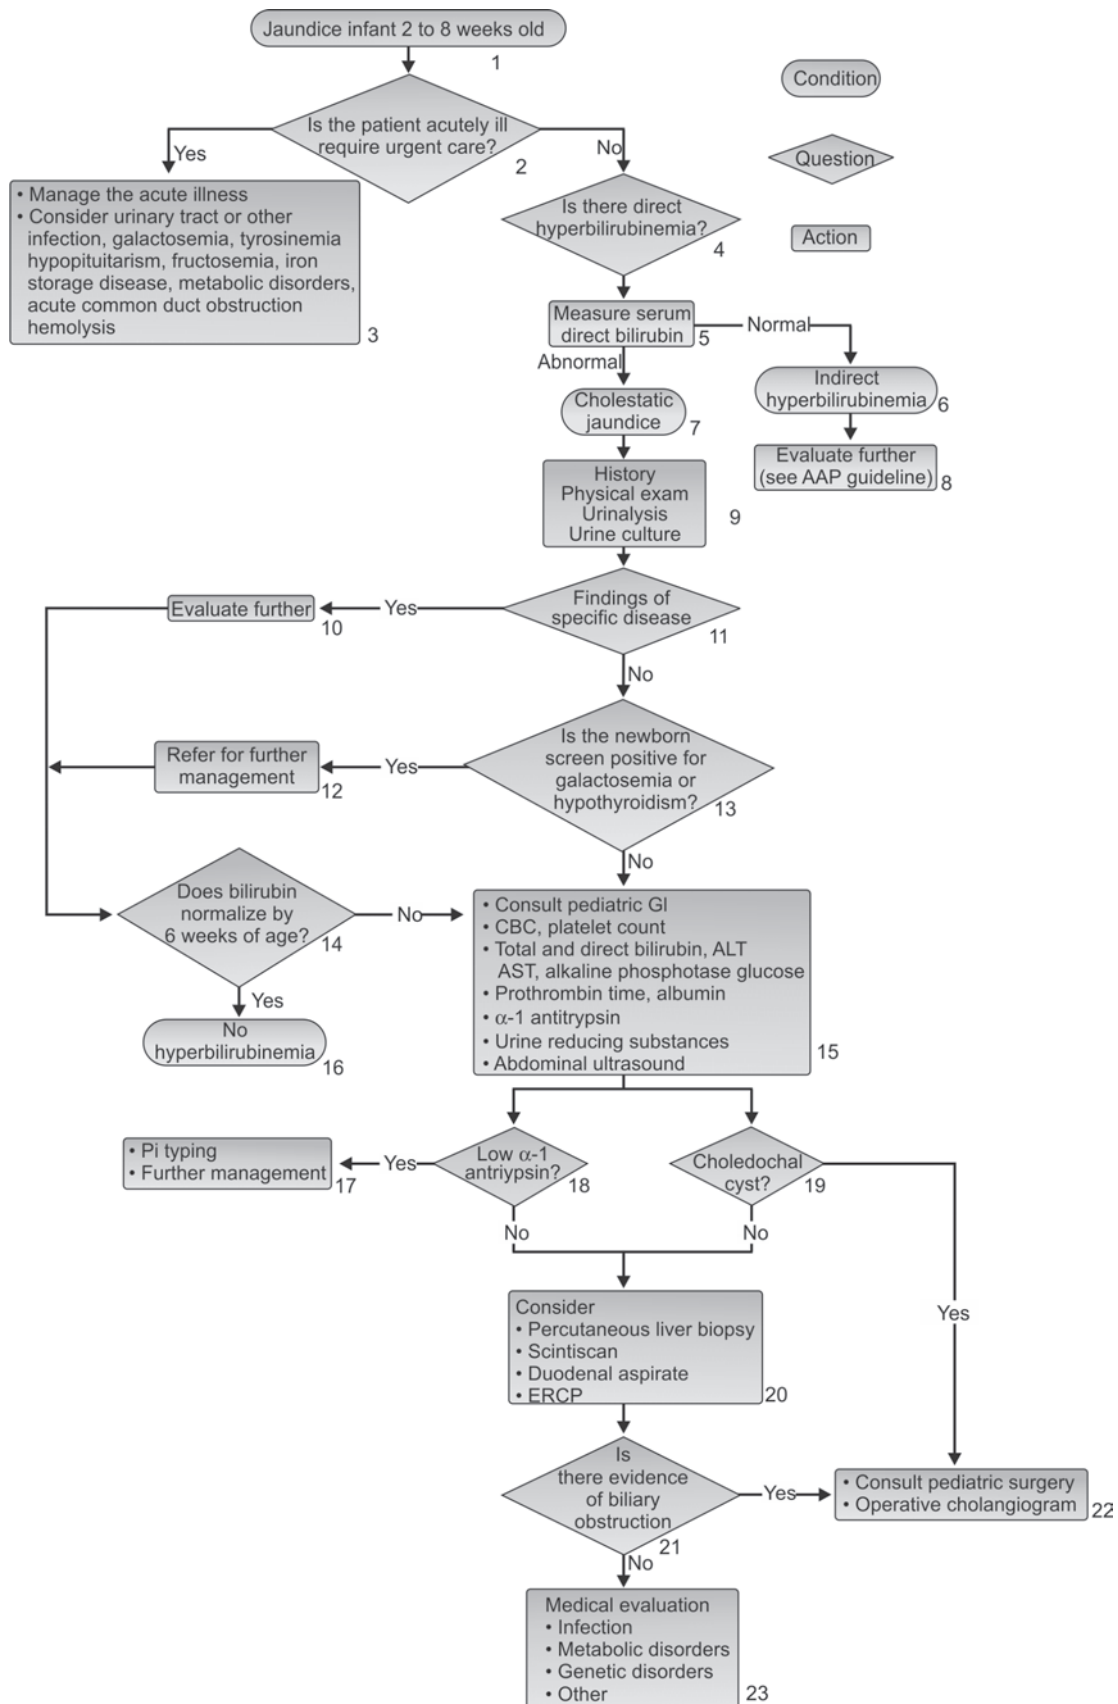

An endoscopic intubation of the biliary tract with contrast injection and radiological evaluation is another method to assess the biliary system with high sensitivity and specificity.⁴⁶⁻⁴⁸ However, due to its limited availability at pediatric centers and size restrictions due to the infant population, it is done only at a few select specialized centers.^{49,50} Alternatively, a magnetic resonance cholangiopancreatography (MRCP) might be another consideration. Though the negative and positive predictive values of MRCP in the detection of biliary atresia are reported at 91 percent and 75 to 96 percent, respectively, it cannot be relied upon exclusively.⁵¹⁻⁵⁵

Liver Biopsy

Due to the relative safety and high yield of the test a percutaneous liver biopsy is a recommendation for most infants with undiagnosed cholestasis. Data suggests interpretation is best if done by pathologists experienced in pediatric liver diseases.⁵⁶⁻⁵⁹ The timing of biopsy is important as results may be equivocal even in patients with biliary atresia if performed before 6 weeks of age.^{56,60,61}

In summary, evaluating neonatal cholestasis is a complex process, however a step by step approach can guide logical decision making. An algorithm developed by the North American Society for Pediatric Gastroenterology, Hepatology and Nutrition Cholestasis Guideline Committee can prove helpful and is recommended by the authors (Flow chart 1). A practicing pediatrician comes across several jaundiced patients and vigilance is crucial in detecting and selecting patients requiring further evaluation. As treatment is directed by the patient status and etiopathogenesis of the underlying condition, it is discussed in subsequent chapters.

Flow chart 18.1: Cholestasis clinical practice guideline. Algorithm for a 2 to 8-week-old infant (North American Society for Pediatric Gastroenterology, Hepatology and Nutrition Cholestasis Guideline Committee)

CHAPTER 19

Recent Advances in the Diagnosis and Management of Neonatal Sepsis

AK Dutta, Ajay Kumar

Neonatal sepsis is one of the most important causes of morbidity and mortality in newborn. Among the low birth weight and preterm babies, neonatal septicemia is the most important cause of mortality especially in developing countries including India. Neonatal septicemia is defined as generalized systemic infection of the newborn, associated with pure growth of bacteria from one or more sites. The exact incidence of neonatal infection in India is not known. There is lack of authentic community data on neonatal sepsis. Bang et al from Gadchiroli district of Maharashtra has reported an incidence of 6.5 percent and 53 percent as a cause of mortality in the newborn period.¹ According to National Neonatal Perinatal Database (NNPD) 2 from hospitals, the incidence ranges from 0.1 percent to 4.5 percent with an overall mortality rate varying from 22 to 30 percent. In the Western literature, the incidence of neonatal sepsis ranges from 0.01 to 0.8 percent.³ With an estimated 25 million births occurring in India and approximately 2 percent incidence of sepsis, the figure for neonatal sepsis in India would be 500,000 babies every year with about one-third, i.e. 170,000 babies succumbing to the disease.

DEFINITION

Neonatal sepsis can broadly classified into early-onset sepsis (<72 hours) and late onset sepsis (>72 hours). Early onset sepsis (EOS) often presents as a fulminant, multi-system illness within 72 hours of delivery and is mainly due to bacteria acquired before and during delivery whereas late onset sepsis (LOS) is due to bacteria acquired after delivery (nosocomial or community sources) and can present as either a fulminant or a smoldering infection. EOS presents with prominent respiratory signs while LOS has more varied presentations.

National Neonatology Forum of India defines neonatal sepsis as follows:

Proven sepsis: The baby presents with clinical picture of sepsis and isolation of pathogens from blood, CSF, urine or other body fluids or autopsy evidence of sepsis.

Probable sepsis: Newborn with clinical picture suggestive of sepsis with one or more of the following criteria:

- Existence of predisposing factors, e.g. maternal fever foul smelling liquor or prolonged rupture of the membrane (>12 hours) or gastric polymorphs more than 6/high power field.
- Positive septic screen (two of the four parameters to be present)
- Total leukocytes count $<5,000/\text{mm}^3$, immature to total neutrophil count ratio >0.2 , C-reactive protein positive and micro ESR $>15 \text{ mm/1st hour}$ or $>\text{age}$ in days + 3.
- Radiological evidence of pneumonia.

Sepsis syndrome: When septicemia is associated with altered organ perfusion (hypoxia, increased blood lactate, oliguria and altered mental state) it is termed as sepsis syndrome. If untreated, this condition leads to early septic shock with decreased capillary refilling and low blood pressure, which can be reversible with appropriate treatment. If untreated this state progresses quickly into refractory shock and leads to multiorgan system dysfunction.

ORGANISMS CAUSING NEONATAL SEPSIS

The etiological agents causing neonatal sepsis vary from region to region and also whether it is community acquired or in hospital set up. It also depends upon the early on set or late onset sepsis. Early onset sepsis is vertically acquired infection from mothers or delivery room settings where maternal gastrointestinal and genital

flora would predominate. In contrast, late onset sepsis is acquired from the environment in the hospital/home and the organisms would be determined by the prevailing microflora of the surroundings. The common organisms reported by NNPD Survey showed 3.8 percent incidence of neonatal sepsis from pooled hospital data with *Klebsiella*, *Staph. aureus*, *Esch. coli*, *Pseudomonas*, *Enterobacter*, Coagulase negative *Staphylococcus*, *Acenatobacter* and *Candida* as the predominant organisms. Group B *Streptococcus*, which is a common etiological agent of early onset sepsis in Western countries is rarely encountered in Indian scenario.^{2,4-7} In the Indian subcontinent, the distinction between EOS and LOS is somewhat blurred.⁸ The clinical presentations of EOS and LOS are different and risk factors are different, but the organisms causing the EOS and LOS are similar and so are their sensitivity profile.^{1,9}

RISK FACTORS FOR EARLY ONSET NEONATAL SEPSIS

Perinatally acquired neonatal bacterial infection usually manifests within the first 3 days of life and is also termed as early onset sepsis. There are several risk factors for neonatal infection.¹⁰ Table 1 depicts the risk factors for sepsis. A good history especially maternal history and elicitation of risk factors are of great importance in the assessment of individual baby and the need for empirical antibiotic therapy. Asymptomatic baby at high risk should receive empiric antibiotic therapy pending culture reports. On the contrary those at low risk should be evaluated and observed. Risk factors are additive and presence of more than two risk factors increases the risk of sepsis manifold (Table 1). Most of the risk factors defined are from the west where group B *Streptococcus* is the etiological agent for early onset sepsis. Some of the risk factors are discussed as follows:

- *Prolonged rupture of membranes (PROM)*: The risk of sepsis in newborns born to mothers with rupture of membranes for more than 24 hours has been reported to be 1 percent compared to a baseline incidence of 0.1 to 0.5 percent.
- *Chorioamnionitis*: It clinically manifests with maternal fever, abdominal/uterine tenderness, foul smelling or purulent amniotic fluid and fetal tachycardia or silent wherein there is histologic evidence of inflammation, but no symptoms or signs. Chorioamnionitis increases the risk of sepsis by 2 to 3 times. A number of diagnostic tests have emerged as markers of chorioamnionitis (Table 2). If PROM is associated with chorioamnionitis, the risk of sepsis increases by four-fold.
- *Prematurity and low birth weight*: Preterm babies are deficient in immunoglobulin concentration, complement function

Table 1: Risk factors for neonatal sepsis

Maternal factors

- Fever
- Urinary tract infection, diarrhea
- Prolonged rupture of the membrane >24 hours.
- Foul smelling amniotic fluid
- Maternal amnionitis
- Maternal genital tract infection and genital colonization
- Socioeconomic factors: Poor socioeconomic status, poor nutrition and hygiene

Neonatal factors

- Preterm and low birth weight
- Perinatal asphyxia
- Vigorous resuscitation
- Invasive procedures
- Congenital malformations, e.g. meningomyelocele
- Male child

Table 2: Diagnostic tests for chorioamnionitis

- Amniotic fluid Gram stain for bacteria, leukocytes ($>50/\text{mm}^3$), culture, leukocyte esterase, glucose concentration $<20 \text{ mg/dl}$, C-reactive protein positive and broad based PCR and IL-6.
- Maternal leukocytosis ($>12,000/\text{mm}^3$), serum C-reactive protein positive, serum IL-6.
- Evidence of oligohydramnios on ultrasound, low biophysical profile.
- Polymorphonuclear leukocytes and intracellular organisms in gastric aspirate of the neonates.

and phagocytic activity. They have 3 to 10 times higher risk of developing sepsis than term infants. Chorioamnionitis may coexist and may trigger for preterm labor. Association of chorioamnionitis and low birth weight increases the risk of sepsis to 16 percent compared to association with normal weight babies.

- *Perinatal asphyxia*: Asphyxia is associated with depressed immune function. In addition, several interventional procedures increase the risk of infection. Presence of low Apgar score (6 or less at 5 minutes) along with prolonged rupture of membranes has shown to increase the risk of infection by 4 percent and 27 percent.
- *Male gender*: Boys have 2 to 6 times higher risk of development of neonatal sepsis.
- *Other factors*: Maternal fever, genitourinary tract infection, poor socioeconomic condition and feeding artificial milk are other risk factors attributed for sepsis.

CLINICAL DIAGNOSIS OF NEONATAL SEPSIS

The early and efficient diagnosis of neonatal bacterial sepsis remains a difficult task since most of the symptoms and signs

of sepsis in the neonatal period are of nonspecific nature. The spectrum and severity of symptoms required to decide in the evaluation of sepsis is a matter of clinical judgement. The symptomatology of sepsis is mostly individual baby to specific and always cannot be dictated by a written protocol. The nonspecific nature of the symptomatology makes it very difficult to clinically diagnose sepsis and if there is delay in initiation of treatment till obvious clinical signs develop, it may be too late to prevent the mortality. On the contrary, if presumptive antibiotic treatment is initiated, there is always a risk of overtreatment. It is estimated that between 11 and 23 noninfected newborns are treated in neonatal intensive care nurseries for every one with documented infection.

The manifestation of sepsis depends on whether it is early onset' or 'late onset' and association of serious bacterial infection, e.g. meningitis, septicemia, pneumonia, bone and joint infection, urinary tract infection and necrotizing enterocolitis. Table 3 depicts differences in early and late onset neonatal sepsis.

The common nonspecific symptoms for possible bacterial sepsis include¹¹⁻¹⁴ respiratory distress, lethargy, fever or hypothermia, hypo- or hyperglycemia, hypotonia, grunting, vomiting, feeding intolerance, abdominal distention, apnea, cyanotic spells, seizures, poor perfusion/shock, petechiae or purpura, unexplained jaundice, or not looking well. Specific data for some of the symptoms are available to aid in decision making. In term babies, respiratory distress after excluding transient tachypnea of newborn is more likely to be secondary to sepsis or pneumonia. The newborn with meconium aspiration syndrome should be considered infective unless proved otherwise. About 10 percent of full term newborns with fever ($>37.8^{\circ}\text{C}$) not due to environmental causes will have bacterial sepsis. Shock, convulsion, bulging anterior fontanelle are other important signs. An unexplained

increase in the serum direct bilirubin concentration may be associated with bacterial sepsis. World Health Organization (WHO) in the integrated management of childhood illness module for young infants 7 days to 2 months of age suggested following criteria to diagnose possible serious bacterial infection¹⁵ (Table 4).

The decision to evaluate and treat a neonate with possible sepsis based on symptoms and signs is a matter of clinical judgment. If a baby looks very sick, develops significant respiratory distress, fever or shock, it should be treated as bacterial sepsis with antibiotic pending culture results. Beyond these, the clinician must rely on careful history with special emphasis on maternal history, thorough physical examination, assessment of severity of symptoms and laboratory investigations.

LABORATORY DIAGNOSIS

Although the isolation of microorganisms from blood, CSF or urine remains the gold standard for confirmation of neonatal sepsis, several nonculture methods of diagnostic tests have been developed with very good sensitivity and negative predictive value. In relation to neonatal sepsis following terms needs little elaboration.

- *Sensitivity*: If infection is present, how often is the test result abnormal?
- *Specificity*: If infection is absent, how often is the test result normal?
- *Positive predictive value*: If the test result is abnormal, how often is the infection present?
- *Negative predictive value*: If the test result is normal, how often is infection absent?

Following table (Table 5) shows the calculation of diagnostic value of tests:

Table 3: Differences in early and late onset sepsis

	Early onset	Late onset
• Time of onset	Less than 72 hours	>72 hours
• Complication of pregnancy/delivery	Present	May or may not be present
• Source of organism	Maternal genital tract	Hospital environment
• Usual clinical presentation	Fulminant multi-system	Slowly progressive
• Meningitis	Rare	Common
• Organisms	<i>Esch. Coli</i> , <i>Klebsiella</i> , <i>Proteus</i> , <i>Staph. aureus</i> Coagulase negative <i>Staph.</i>	<i>Klebsiella</i> , <i>Staph aureus</i> , coagulase negative <i>staph.</i> , <i>Pseudomonas</i> species.
• Mortality	30-50%	15-30%

Table 4: Classification of sick young infants for bacterial infection (WHO)

Signs	Classify as
<ul style="list-style-type: none"> • Convulsion or • Fast breathing (60 breaths per minute or more) or • Severe chest in-drawing or • Nasal flaring or • Grunting or • Bulging fontanelle or • Pus draining from ear or • Umbilical redness extending to skin or • Fever (37.5°C or above or feels hot) or low body temperature (less than 35.5°C or feels cold) or • Many or severe skin pustules or • Lethargic or unconscious or • Less than normal movement 	→ Possible serious bacterial infection
<ul style="list-style-type: none"> • Red umbilicus or draining pus • Skin pustules 	→ Local bacteria infection

Table 5: Interpretation of diagnostic value of tests

Screening test	Blood culture positive	Blood culture negative	Total
CRP +ve	a (80)	b (50)	All CRP +ve $a + b = 130$
CRP -ve	c (20)	d (150)	All CRP -ve Babies $c + d = 170$
Total	All septic babies $a + c = 100$	All nonseptic babies $b + d = 200$	All babies $a + b + c + d = 300$

Sensitivity of CRP test would be = Proportion of septic babies (Blood culture +ve) who are CRP +ve = $a/a+c = 80/100$ or 80 percent. This is also known as true positive rate.

Specificity = Proportion of nonseptic babies who are CRP -ve = $d/b+d = 150/50+150 = 75$ percent. This is also known as true negative rate.

Positive predictive value = Proportion of CRP+ve babies who are septic = $a/a+b = 80/80+50 = 61.5$ percent.

Negative predictive value = Proportion of CRP -ve babies who are nonseptic = $c+d/c = 20+150/20 = 85$ percent.

Diagnostic tests with maximal (100%) sensitivity and negative predictive value are desirable for diagnosis of neonatal sepsis. This indicates if infection were present, the result would be always abnormal and if results were normal, infection would always be absent. A good specificity and positive predictive value is also acceptable.

Definitive, Specific Diagnostic Tests

Isolation of organism from blood or a central body fluid is the standard and most specific method to confirm the diagnosis of neonatal sepsis. The main drawback is that, the results are available after 48 to 72 hours. Another dilemma often faced by the clinicians is the high percentage of cases (up to 40%) where no bacteria can be isolated from blood even in highly suspected cases of sepsis.

Blood Culture

The standard microbiological procedure is to collect about 1 ml of blood by sterile venepuncture in a blood culture bottle. If, there is already umbilical arterial catheterization, blood sample can be collected from the indwelling catheter but collection of blood from an indwelling umbilical venous catheter is not reliable. The blood culture should be incubated for at least 72 hours before being considered negative. In a study conducted by Geme JW¹⁶ et al, 13 percent of positive blood culture did not grow until beyond 72 hours. The late growing organisms were anaerobes and coagulase negative staphylococci. Blood culture although considered to be “gold standard” in the confirmation of diagnosis of septicemia has been found to

be negative in 20 percent cases where infection was proven by immediate postmortem culture and autopsy.^{17,18} In the mildly symptomatic neonate and at the earliest onset of septicemia, the false negative blood culture rate would be very high. In addition, up to 50 percent of the cases with congenital bacterial pneumonia proved by tracheal aspirate culture, blood culture is negative. Therefore blood culture should not be considered as the final arbiter for the clinical diagnosis of neonatal infection.

Automated systems for continuous monitoring of blood cultures coming into routine use have shortened the time to identify positive blood cultures. In most cases of neonatal sepsis, a blood culture will become positive within 24 to 36 hours. This was illustrated in a study of 455 positive blood cultures from 222 preterm and term infants evaluated for neonatal sepsis. An automated blood culture system identified 77, 89, and 94 percent of all microorganisms within 24, 36, and 48 hours of incubation in aerobic conditions, respectively.¹⁹

In a prospective observational study from India, 101 cases of suspected neonatal sepsis were used to compare the manual method of blood culture with an automated BacT/Alert system for detection of neonatal septicemia. The mean times to positivity with the manual and BacT/Alert 3D systems were 53.1 h and 14.3 h, respectively ($p < 0.001$). With conventional methods the detection rate is 89.1 percent by day 2 and 99.5 percent by day 4.²⁰

Cerebrospinal Fluid Examination and Culture

All neonates with suspected septicemia as a primary diagnosis should have a lumbar puncture.^{21,22} Newborns suffering from meningitis may have specific symptoms and 20-30 percent of neonates with sepsis may have associated meningitis. Moreover, 15 percent of babies with positive CSF culture may have negative blood culture. The interpretation of CSF cytology and biochemistry in newborn is often difficult.

The concentration of glucose is not significantly altered by a traumatic lumbar puncture. Therefore a low CSF glucose in the setting of a traumatic LP is abnormal. Nothing much is gained by using the various formulas for adjusting the WBC count in a traumatic CSF, based on the RBC counts. Adjustment merely results in a loss of sensitivity with marginal gain in specificity.²³ Ideally, the WBC cell count must be performed within 30 minutes of drawing the sample. It must be noted that CSF WBC and glucose rapidly fall with time, giving spurious results.²⁴

Traditionally, the following cut-offs have been used: 30 cells, more than 60 percent of polymorphs, glucose less than 50 percent of blood glucose, protein more than 150 mg/dl in term babies and 180 mg/dl in preterm babies.

Urine Culture

Urine culture by bag specimen is highly unreliable and should not be obtained by this method. The urine specimen

should be obtained by sterile bladder tap only in suspected cases of urinary tract infection. Urine culture sample is very difficult to obtain and has a very low yield of organism especially in first 72 hours.²⁵

Tracheal Aspirates

Tracheal aspirate samples are useful in first 12 hours of life. Sherman²⁶ et al demonstrated that a positive tracheal culture may be found in 44 percent of babies with pneumonia where blood culture was sterile. Furthermore, there is a positive correlation of tracheal aspirate Gram stain for bacteria with clinical or pathological pneumonia and has a 47 percent predictive accuracy in bacteremic infants.

Polymerase Chain Reaction

Polymerase chain reaction (PCR) is a definite advancement in the armamentarium in the diagnosis of bacterial infection. However, the prohibitive cost and difficult technique precludes its use in the routine evaluation of neonatal sepsis.

Latex Particle Agglutination Test

Latex particle agglutination test (LPA) is a relatively simple test to perform but is not very sensitive. The standard kits for group B *Streptococcus*, *Pneumococcus* and *Meningococcus* are available and hence can not be used routinely.

Nonspecific Diagnostic Septic Screening Tests

The difficulties in accurate diagnosis of neonatal septicemia have prompted investigators to evaluate many adjunctive diagnostic tests many of which can be done in the clinical side laboratories that may indicate infection without identifying the infecting organisms. Because of the severity of the disease, it is essential for these indirect tests not to miss any case (have 100% sensitivity) and to rule out convincingly sepsis when it is not present (have a high negative value). Therefore, to achieve both the above goals, one must be willing to treat some infants who are truly not infected. A battery of tests have been evaluated either alone or in combinations in order to improve diagnostic accuracy.²⁷⁻³⁰ Table 6 summarizes the tests and their sensitivity and specificity.

White Blood Cell Count

The work of Manroe et al²⁷ has increased the utility of this test through the establishment of normal reference ranges for total neutrophil counts and indices of immature neutrophils. A total leukocyte count of $<5000/\text{mm}^3$, total neutrophil count of $>1750/\text{mm}^3$ and an immature to total neutrophil count ratio (I/T) of >0.2 are suggestive of sepsis. From the study by Schelonka et al,³¹ the normal ranges for leukocyte indexes in 193 healthy term infants with no identifiable perinatal risk factors

for infection were at 4h of life considerably broader than those described previously by Manroe et al. Thus, if one applies the reference intervals of Manroe et al to healthy term infants, one would label huge numbers of them as being at extremely high risk for sepsis. It is important to remember that the actual physical sampling can lead to dramatic changes in the CBC results. It has been well documented that the CBC depends on the infant's age, on whether the sample is arterial or venous, and on whether the infant is crying vigorously.^{27,31,32} This means that for a given infant, a test value is not a static value; there is considerable intraindividual variability.

However, the wide range of predictive values in Table 6 are explained by many factors. Some studies have combined proven sepsis patients with suspected sepsis. In addition maternal hypertension, perinatal asphyxia and intraventricular hemorrhage may cause neutropenia. Nonspecific stresses such as asphyxia, maternal fever or stressful labor can elevate the I/T ratio. Very few studies have shown that the presence of neutrophil vacuolization or toxic granulation are also good indicators of neonatal sepsis.³³

C-reactive Protein (CRP)

C-reactive protein (CRP) is a rapidly responsive acute phase reactant, which is synthesized by the liver within 6-8 hours of stimulus of inflammatory process. It can be performed in the side laboratory by a positive CRP latex agglutination test on an undiluted sample, which corresponds to a plasma CRP concentration of 0.8 to 1.0 mg/dl. A single value of negative CRP done at the onset may not be of much significance. Therefore, in suspected sepsis, a repeat CRP test done 12 hours later is more significant. If the test is negative — it almost excludes sepsis. CRP also has a very important role in prognosis of sepsis. Normalization of CRP is a helpful tool in determining the response to antimicrobial therapy and duration of treatment. Failure to mount a CRP response is a poor prognostic sign.

Erythrocyte Sedimentation Rate

Micro-ESR is an inexpensive and easy bedside screening test for neonatal sepsis. Normal values increase with postnatal age and are equal to the day of life plus 3 mm/hour up to a maximum of 15 mm/hour. Erythrocyte sedimentation rate (ESR) is less sensitive but more specific than CRP or I/T ratio.

Other Acute Phase Reactants

Haptoglobin and orosomucoid are acute phase reactants that have been evaluated for diagnostic aids for neonatal sepsis, but their utility is limited because of their slower response to infection. A low plasma fibronectin concentration (an opsonic glycoprotein) is suggestive of neonatal sepsis. Plasma fibronectin is also depressed by respiratory

distress syndrome and perinatal asphyxia thus limiting its use.

Miscellaneous Tests

- Elastase-alpha-1-proteinase inhibitor complex rises rapidly in the course of infection and is 100 percent sensitive although not highly specific.
- C3D is a major byproduct of complement activation by endotoxin or antigen antibody complexes and is elevated in infected neonates.
- Endotoxin, which can be measured by Limulus amoebocyte lysate test is found in the plasma of many neonates with infection.
- Direct visualization of bacteria in neutrophils stained by acridine orange is an important diagnostic test in neonatal sepsis.
- Neutrophils from septic patients may reduce the dye nitroblue tetrazolium (NBT) more quickly than those from normal healthy patients.
- Gastric aspirate for polymorph count and culture has limited value in the diagnosis of neonatal sepsis. However, this test is indicative of high risk because of exposure to chorioamnionitis.

NEWER DIAGNOSTIC MODALITIES

Procalcitonin

A propeptide of calcitonin, is released into the blood 3 to 6 hours after endotoxin injection and increases up to 24 hours; the increase does not correlate with calcitonin levels and occurs even in subjects who have had thyroidectomy. Very high serum procalcitonin levels are present in neonates with proven or clinically diagnosed bacterial infection; early decrease of these concentrations reflects appropriate antibiotic therapy.³⁴ Compared with CRP, procalcitonin has the advantage that it increases more rapidly; however, the significant rapid variations of basal levels after birth, and the need for several different cut-off values with changing neonatal age, have limited the diffusion of this marker in comparison to the CRP.³⁵ Nevertheless, a recent meta-analysis suggested that procalcitonin showed better accuracy than the CRP test for the diagnosis of late-onset sepsis.³⁶

Cytokines and Receptors

The cascade of events initiated by the bacterial infection starts with the activation of macrophages thereby releasing several inflammatory cytokines and growth factors. The cytokines released are tumor necrosis factor (TNF- α), interleukin beta (IL- β) and interleukin-6 (IL-6). Interleukin-3 (IL-3) and colony stimulating factors (CSFs) are the growth factors liberated by the macrophages. These mediators trigger the inflammatory reaction with formation of acute phase reactants by the liver and activation of

Fig. 1: Band cell: The ratio A:B should be more than 1/3 to differentiate it from segmented polymorphonuclear cell

neutrophils. The increase in cytokines levels is therefore observed much earlier than the hematological values (Fig. 1). Several cytokines have been evaluated for the early diagnosis of neonatal sepsis.

Interleukin-6 (IL-6) and interleukin-1 receptor antagonist (IL-1ra) are two important diagnostic markers for neonatal sepsis. The level of these two markers increases 2 days before clinical diagnosis of sepsis. IL-6 although is a very early marker, the level becomes normal later even if infection continues. The simultaneous determination of CRP can obviate this problem because the rise in plasma CRP levels occurs 12 to 48 hours after the onset of infection, at a time when IL-6 level would have fallen.

Specific Leukocyte Surface Antigens

They are known to be expressed in substantial quantities after inflammatory cells are activated by bacteria or their cellular products. In newborns, cell surface antigens have been studied in connection with congenital, early and late onset sepsis. Neutrophil CD11b and CD64 have been found to be promising markers for diagnosis of early and late infections respectively. CD11b is a subunit of the b2 integrin adhesion molecule. It is normally expressed at a very low concentration on the surface of nonactivated neutrophils.^{37,38} Its expression, however, increases considerably within a few minutes after the inflammatory cells come into contact with bacteria and endotoxins.^{39,40}

CD64 is a highly effective marker for the diagnosis of late onset infection.³⁷ CD64 is normally expressed in very low concentrations by unstimulated neutrophils. It is considerably upregulated on the trigger of bacterial invasion³⁷ and has been shown to be involved in the process of phagocytosis and intracellular killing of pathogens. More importantly, neutrophils from preterm infants express CD64 during bacterial infections to the same degree as those from term infants, children, and adults.³⁷

Granulocyte colony stimulating factor (G-CSF) is a hematopoietic growth factor produced by several types

of cells such as monocyte-macrophages, epithelial cells, endothelial cells and fibroblasts. Polysaccharide is a major stimulus for G-CSF production in sepsis. The higher level of G-CSF has been found to be associated with a sensitivity of 95 percent for prediction of sepsis and a specificity of 73 percent if the level is >200 pg/ml.

The best combination for newer markers for sepsis would be estimation of IL-6 and IL-1ra one to two days before the onset of symptoms. IL-6, IL-1ra, IL-8, CD 11b, G-CSF, TNF, CRP and hematological indices on day 0, CRP, IL-6 (or G-CSF) and hematological indices on day 1, and CRP on the following days to monitor response to treatment. CD64 is probably one of the most useful infection markers for diagnosis of late onset nosocomial sepsis. In addition, the use of multiple markers, in particular, combining an early sensitive marker with a late specific test will further enhance the diagnostic accuracy of these mediators in identifying infected cases. These promising markers may be used for early termination of antibiotic treatment in noninfected infants. However, none of the current diagnostic markers are sensitive and specific enough to influence the judgment to withhold antimicrobial treatment independent of the clinical findings. Until further evidence from larger studies are available, daily routine screening for prediction of neonatal infection is not warranted.

Broad Based PCR

A broad based PCR with amplification of bacterial DNA, i.e. 16 Sr DNA has been used for identification of bacteria but the cost is prohibitive.

WBC—White blood cell count; I/T—immature to total neutrophil ratio; CRP—C-reactive protein; ESR—Erythrocyte sedimentation rate – NBT—Nitro blue tetrazolium dye test (Flow chart 1).

Anti-inflammatory cytokines: IL-4, IL-10, TGF-B1, G-CSF. Inhibition of T.

Sepsis Screen

As is evident from Table 6, no single test is of high diagnostic value. Therefore, a combination of at least 2 or more tests, if abnormal, leads to an increase in predictability for early onset sepsis. Sepsis screen has been found to be cost effective in decreasing the use of antibiotic in the nursery.

Proteomics and Genomics

Modern applications of molecular pathology embraces various disciplines: genomics (sequence DNA), transcriptomics (mRNA identification), proteomics (protein identification) and pharmacogenomics (genes that define the behavior of drugs). Proteomics is the study of expressed proteins in a tissue, cell, or organism at a given moment. It is clinically more significant and easier to translate into diagnostic tools and therapeutic strategies than genomics, which studies DNA.

The science of proteomics has been applied to the search for biomarkers and production of protein profiles that can rapidly help the prediction, early diagnosis, and

Flow chart 1: Cytokines and acute phase reactants

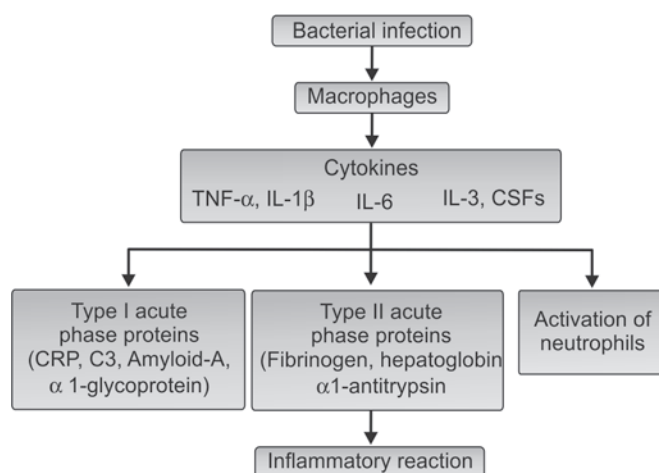

Table 6: Performance of adjunctive tests in diagnosis of neonatal sepsis

treatment of human diseases.⁴¹ To analyze proteomics data from SELDI-TOF (surface enhanced laser desorption ionization time-of-flight) outputs, Buhimschi et al.⁴² developed a strategy to extract significant proteomic biomarkers characteristic for intra-amniotic inflammation, based on sequentially applied filter preferences. This strategy was called mass restricted (MR) scoring. The MR score indicate the number of identifiable markers among the following factors of innate immunity: neutrophil defensin-2, neutrophil defensin-1, S100A12 (calgranulin C) and S100A8 (calgranulin A).⁴² An MR score of 3 to 4 indicated the presence of inflammation, while a score of 0 to 2 excluded it. An MR score of 3 to 4 had the highest accuracy (92.6%) in diagnosing intra-amniotic inflammation, and was significantly better than white blood cell (WBC) count or IL-6.

Molecular techniques: There are also molecular-based approaches for diagnosis of neonatal infection:

- Whole blood directly tested by target amplification;
- Whole blood pre-enrichment before target amplification;
- Fluids from positive blood culture bottles tested by polymerase chain reaction (PCR);
- Nucleic Acid Sequence Based Amplification (NASBA);
- Nucleic Acid Amplification Tests (NAATs);
- PCR in conjunction with sequencing or microarray analysis;
- Nonamplification-based fluorescence in situ hybridization (FISH).

The sensitivity and specificity of real-time PCR assay was 96.2 percent and 100 percent respectively,⁴³ with a limit of recognition for *E. coli* and group B Streptococcus, while in another study that targeted several larger 16S rDNA, was 66.7 percent and 87.5 percent.⁴⁴

Genetic Polymorphism

The possibility of understanding the genetic contribution to response to microbial pathogens remains one of the most stimulating prospects of the unravelling of the human genome. The identification of strong associations between certain genetic polymorphisms and susceptibility to severe sepsis supports further research using appropriate association studies.⁴⁵

Recent evidence that the genetic background of the host affects the systemic response to infection has stimulated considerable interest in the evaluation of genetic susceptibility to sepsis, concerning in particular factors of the initial immune response of the innate immunity, as Toll-like receptors (TLRs), mannose-binding lectin (MBL), nucleotide-binding oligomerization domains (NODs) and cytokines.⁴⁶⁻⁴⁸

A recent meta-analysis assessed the evidence for the association of the IL-6 (-174C) polymorphism (guanidine to cytosine transition at position -174 nucleotides relative

to the transcription start site in the interleukin-6 gene) with the risk of sepsis in very light birth weight (VLBW) newborn infants. The results of six cohort studies including a total of 1323 VLBW infants found no significant association between carriage of the IL-6 (-174C) polymorphism and sepsis: pooled relative risk 0.90 (95% CI 0.62 to 1.31). These data did not support screening infants for this allele in order to guide selective antimicrobial prophylaxis.⁴⁹

MANAGEMENT PROTOCOL

Symptomatic Neonate

If the clinician has a suspicion that the baby is having probable or suspected sepsis then the baby should be immediately started on antibiotics. Here, the risk factors or maternal pretreatment with antibiotic is immaterial. The choice of antibiotic would depend upon the prevalence of organism in a particular set up and their antibiogram pattern. In most centers in India and the world, the first line of antibiotic is usually a combination of Inj. Ampicillin and Inj. Amikacin or Gentamicin. Simultaneously sepsis screening is performed, blood and CSF cultures are sent and a chest X-ray is performed. If the mother has been receiving antibiotic treatment, then irrespective of the result of the screening test and culture report (positive or negative), antibiotic treatment is continued for 7 to 10 days in case of pneumonia, 10 to 14 days for septicemia and 14 to 21 days for meningitis. If however, there was no maternal pretreatment with antibiotic and sepsis screen is normal and cultures are sterile and baby is normal, the antibiotic may be discontinued after 72 hours if baby is clinically stable (Flow chart 2).

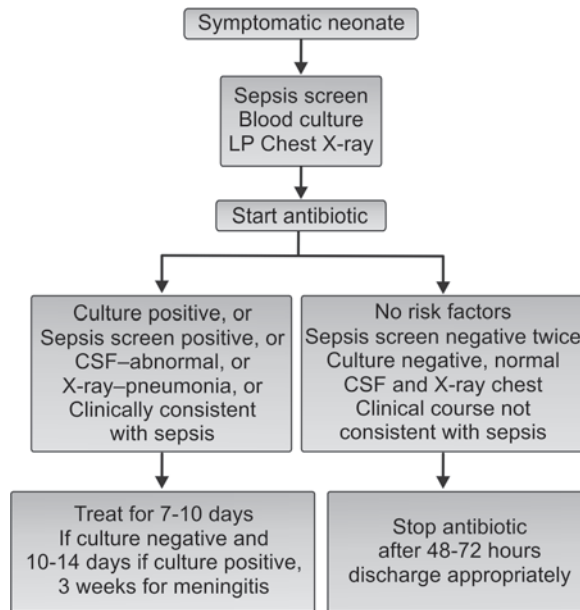

After the culture and sensitivity report is available and depending upon its pattern, antibiotic is changed. If there is clinical deterioration, irrespective of the investigation report, the second line of antibiotic i.e., a third generation of Cephalosporin and an aminoglycoside e.g., gentamicin, amikacin or netromycin are given. In case meningitis is suspected, third generation cephalosporin is started from the very beginning.

Asymptomatic Neonate

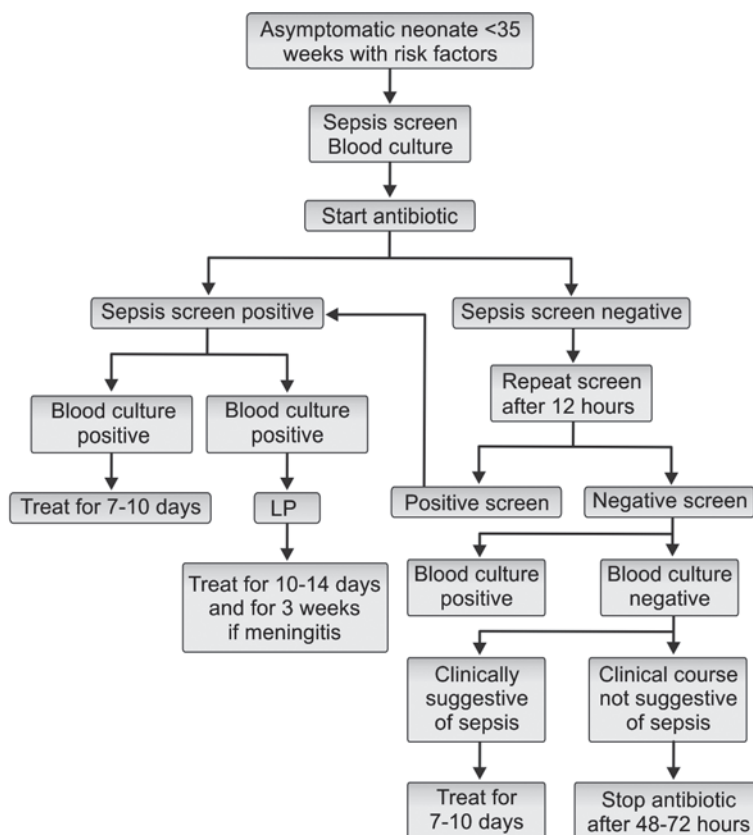

If the baby is asymptomatic and is a low-risk newborn for sepsis (one or 2 risk factors) then the baby should be observed clinically for 48 hours and a sepsis screening performed. If the baby is asymptomatic and is a high risk for infection (>3 risk factors), then sepsis screening is done and antibiotic started. If the sepsis screen is positive or negative and blood culture is negative and the mother did not receive any pretreatment, the antibiotic is discontinued after 72 hours. However, if the culture is positive, antibiotic is continued as for symptomatic baby. On the other hand, if the mother has received antibiotic

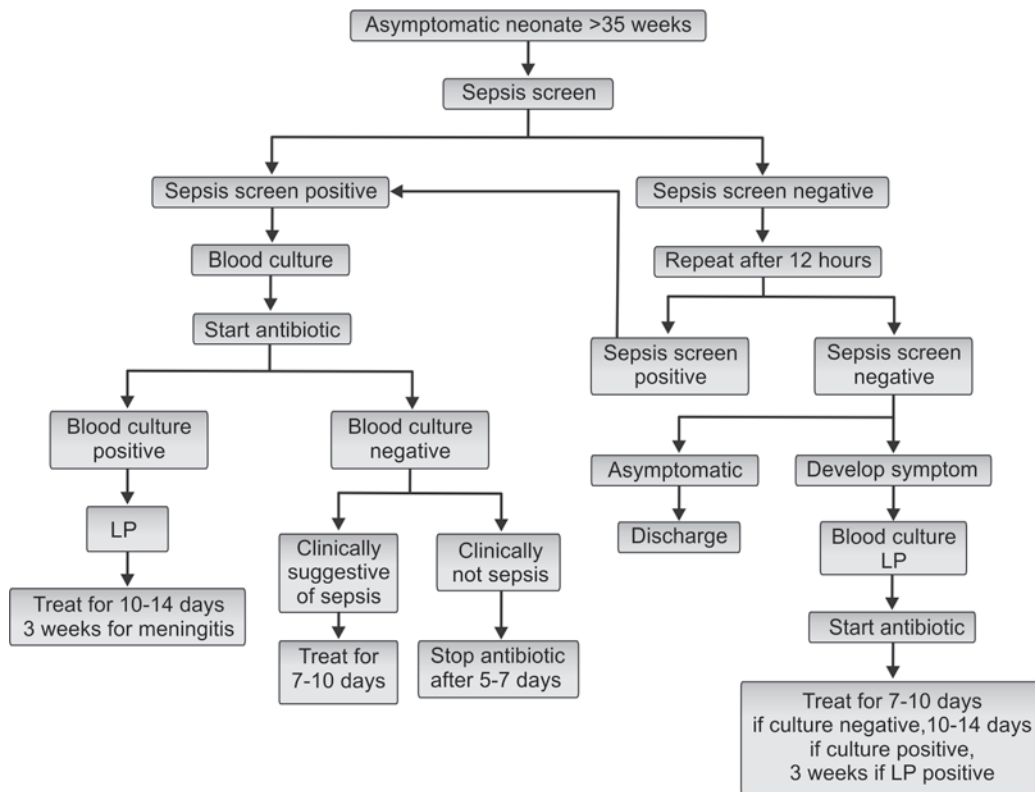

and the sepsis screen and/ or culture is positive then antibiotic is continued as in symptomatic baby and the antibiotic is discontinued after 72 hours if the screening tests and culture is normal (Flow charts 3 and 4).

Flow chart 2: Approach to a symptomatic neonate

Flow chart 3: Approach to asymptomatic neonate <35 weeks gestation with one or more risk factors

Flow chart 4: Asymptomatic neonate 35 weeks gestation or more with one or more risk factors

ANTIBIOTICS IN NEONATAL SEPSIS

The choice of empirical use of antibiotics for neonatal septicemia depends upon many factors, e.g. availability, affordability, community acquired or nosocomial, antibiotic sensitivity pattern of the nursery and the type of infection. In clinical practice for community acquired neonatal sepsis the first line of drug is usually a combination of aminoglycoside, i.e. gentamicin, amikacin or netromicin along with ampicillin or crystalline penicillin. If the condition does not improve, then third generation cephalosporin is added to the aminoglycoside and ampicillin is stopped. In contrast in hospital acquired neonatal sepsis, a combination of aminoglycoside and third generation cephalosporin is the drug of choice. If antibiotic sensitivity pattern is known, then choice of the drug is made accordingly. With the advent of several newer generations of antibiotics, there is a general tendency to use latest drugs, which is not always warranted. Rational use of antibiotics is essential to reduce the long-term effect of emergence of drug resistance and economic burden to the family. There are several antibiotics available and are used routinely in neonatal septicemia. Table 7 depicts the antibiotics and their doses in newborn period.

SUPPORTIVE THERAPY

Apart from antimicrobial therapy, supportive and symptomatic care is of vital importance for the intact survival of these babies.

The supportive therapy includes the following:

- Temperature regulation
- Careful management of fluid and electrolyte, normoglycemia, acid base status and oxygenation.
- Nutritional management
- Control of seizures if occur
- Management of shock if it develops
- Blood and blood component therapy if indicated.
- Early surgical intervention in case of septic arthritis, peritonitis and necrotizing enterocolitis.

NEWER MODALITIES IN THE TREATMENT OF NEONATAL SEPSIS

Intravenous immunoglobulin (IVIG): Some investigators have attributed high rates of sepsis in neonates to low levels of IgG immunoglobulin and have hypothesized that intravenous immunoglobulin therapy in the neonate is an acceptable approach for treatment. Similar to most

Table 7: Antibiotics, antifungal and antiviral agents and their doses in neonates

immunoglobins, the transplacental transport of IgG from the mother to fetus begins around 32 weeks gestation and increases until term. Premature infants born prior to 32 weeks gestation have profound IgG deficiencies.

It has been demonstrated that administering immunoglobulin concurrent with antibiotics was more effective in treating neonatal sepsis than administering antibiotics alone. The mortality rate of preterm infants receiving antibiotics supplemented with immunoglobulin was 10 percent (2/20) compared to those receiving antibiotics alone 26 percent (4/15), and no term infants died. Follow-up of the experimental groups at one and five years demonstrated no adverse sequelae from immunoglobulin therapy.⁵⁰ A larger follow-up study in 130 septic neonates comparing intravenous IgM to IgG adjuvant therapy with concurrent antibiotic therapy demonstrated no significant difference in survival between the two formulations while both improved mortality rates compared to nonimmunoglobulin treated groups.⁵¹

There are several published data⁵²⁻⁵⁴ on the use of IVIG in neonatal sepsis both for prophylaxis as well as for treatment in preterm as well as in term babies. The prophylactic benefit of immunoglobulin therapy was assessed by Baker's group in 1989 with a double blinded study of 588 low birth weight neonates. Although, there was no

difference in mortality rate, those neonates transfused with immunoglobulin demonstrated a reduction in the incidence of infection (relative risk of 0.7), fewer days of total hospitalization (62 v. 68d), and fewer days of hospitalization for septic neonates (80 v. 101d).⁵⁵ A recent Cochrane Meta-Analysis by Ohlsson concluded that prophylactic IVIG produced a 3 percent reduction in sepsis and a 4 percent reduction in other incidences of severe infection but did not lead to any difference in mortality rate.⁵⁶

A recent RCT done by INIS Collaborative Group included 3493 infants from 113 hospitals in nine countries and who were receiving antibiotics for suspected and proven bacterial infection. They were randomly assigned to receive two infusions of either polyvalent IgG immune globulin (at a dose of 500 mg per kilogram of body weight) or matching placebo 48 hours apart. The primary outcome was death or major disability at the age of 2 years. There was no significant between-group difference in the rates of the primary outcome, which occurred in 686 of 1759 infants (39.0%) who received intravenous immune globulin and in 677 of 1734 infants (39.0%) who received placebo (relative risk, 1.00; 95% confidence interval, 0.92 to 1.08). Similarly, there were no significant differences in the rates of secondary outcomes, including the incidence

of subsequent sepsis episodes. In follow-up of 2-year-old infants, there were no significant differences in the rates of major or non major disability or of adverse events. They concluded that therapy with intravenous immune globulin had no effect on the outcomes of suspected or proven neonatal sepsis.⁵⁷

In the light of the available data, use of IVIG to prevent or treat neonatal infection is not routinely recommended. However, there may be clinical situations in which a clinician might consider use of IVIG therapy (the sick preterm baby with overwhelming sepsis) or for prophylaxis in a preterm baby with low IgG level and recurrent infection. A dose of 500 to 1000 mg/kg/dose would be appropriate for both situations and the dose should be repeated every 2 weeks till improvement.

Granulocyte colony stimulating factor (G-CSF) and granulocyte-monocyte colony stimulating factor (GM-CSF): Both these agents have been found to be promising in some trials.^{58,59} Recently a multicenter trial by Kuhn et al, including 200 infants, studied the benefit of prophylactic rG-CSF treatment in preterm neonates with neutropenia in preventing nosocomial infections during 4 weeks of treatment. Although rG-CSF increased the number of neutrophils in these patients during the initial two weeks of treatment, this difference did not persist to the conclusion of the study. Kuhn et al concluded that prophylactic rG-CSF did not increase infection free survival four weeks after initiating treatment.⁶⁰ rG-CSF prophylaxis however may prove beneficial in bolstering neutrophil number and preventing infection in some subsets of neonates including those that are small for gestational age and those with early established postnatal neutropenia.⁶¹⁻⁶³ However, in spite of proliferative and functional benefits GM-CSF on the neonatal neutrophil population, rGM-CSF administration does not significantly increase sepsis free survival and there is insufficient evidence to support its use both as a prophylactic and treatment strategy.⁶⁴

White blood cell transfusion: Some scientists have forgone attempts to treat neonatal sepsis by stimulating the proliferation and function of existing neonatal neutrophil precursors and have instead administered adult neutrophils to at risk neonates. The first documented granulocyte transfusion in neonates was performed by Laurenti et al. In their trial, they transfused 20 neonates suffering from systemic *Klebsiella* infections with granulocytes acquired from adults. Results found significant reductions in mortality, 10 percent in transfused groups and 72 percent in non-transfused groups.⁶⁵ A trial by Cairo et al in 1992, where they compared granulocyte transfusion to IVIG transfusion for the treatment of sepsis in neutropenic neonates. This trial including 35 infants found 100 percent survival (21/21) in the granulocyte treated group and 64 percent survival (9/14, $p < 0.03$) in the IV immunoglobulin treated group.⁶⁶ However, the 2003 Cochrane review by Mohan

and Brocklehurst questioned the efficacy of granulocyte transfusions. They determined that the relative risk of eligible trials was not significantly different in all-cause mortality when compared to placebo. They did however agree that the increased protection of granulocyte transfusion over IV immunoglobulin use determined in the 1992 Cairo trial was of borderline statistical significance. The limited statistical significance was attributed to a small number of trials with relatively few study subjects.⁶⁷

Blood exchange transfusion (BET): Double volume BET has been used as a modality for managing sepsis for several decades, but large, well-conducted RCTs are still lacking. The earlier trials were uncontrolled and showed impressive improvements in neutrophil counts, immunoglobulin levels, recovery from sclerema and less mortality compared to historical experiences.^{68,69} In a small RCT from India, conducted on septicemic neonates, there was a non significant reduction in mortality [7/20 versus 7/10; RR 0.5 (95% CI 0.24, 1.03)], but there were significant improvements in total leukocyte count, absolute neutrophil count and neutrophil functions in the BET group.⁷⁰ In another small RCT on sclerematous neonates from the same centre, BET resulted in a significant reduction in mortality [50% versus 95%; RR 0.53 (95% CI 0.34, 0.83)] and significant improvement in immunoglobulin levels.⁷¹ BET may be performed in a case of deteriorating sepsis with sclerema provided the general condition of the baby allows the procedure.

On-line plasma exchange and hemofiltration: As an alternative to exchange transfusion the above modality has been tried in experimental models with encouraging results.

Strategies for treating septic shock in neonates: A number of therapeutic products are being used in the treatment of septic shock, e.g. monoclonal antibodies to tumor necrosis factor (TNF α) and interleukin-1 (IL-1) in animal models. In addition, pentoxifylline, a phosphodiesterase inhibitor has been tried which decreases the production of TNF- α . The role of prostaglandins, ibuprofen, ketoconazole and inhibitors of nitric oxide synthase would need further evaluation in the management of septic shock (Table 8).

PROGNOSIS

Prior to the availability of antibiotics, almost all infants with sepsis died. Outcome data for group B streptococcal (GBS) neonatal sepsis after the introduction of intrapartum antibiotic prophylaxis and the routine use of empirical antibiotic therapy demonstrate an overall fatality rate between 5 and 10 percent. However, mortality is lower in term infants with case fatality rates for early-onset disease, ranging from 2 to 3 percent, and from 1 to 2 percent for late-onset disease. Clinical features associated with mortality in early-onset GBS infection include birth weight less than 2500 g, absolute neutrophil count less than 1500 cells/microL, hypotension, apnea, and pleural effusion.⁷²

Table 8: Newer modalities for treating septic shock

- Antiendotoxin, anti-CD14 monoclonal antibodies.
- Anti-inflammatory cytokines: IL-4, IL-10, TGF-B1, G-CSF.
- Inhibition of TNF- α -gene-transcription: Pentoxifylline, Amrinone, Dobutamine, Chlorpromazine.
- Inhibition of TNF- α gene translation: Corticosteroid.
- Inhibition of TNF and IL-1: Anti-TNF, anti-IL-1 monoclonal antibody.
- Inhibition of IL-1 and TNF receptors: IL-1ra, IL-1 and TNF soluble receptors.
- Inhibition of nitric oxide: Arginine analog (L-NAME and L-nmme), Vit B₁₂, Methylene blue.

The mortality rate appears to be higher in neonates with early-onset *Escherichia coli* (*E. coli*) sepsis, as illustrated by the following studies: In a retrospective review of all the neonatal cases of early-onset *Escherichia coli* (*E. coli*) sepsis at a single Spanish center from 1992 to 2002, the mortality rate for term infants was 4 percent.⁷³ In a retrospective case-control study, cases of *E. coli* sepsis in infants less than seven days of age were identified in selected counties of California, Georgia, and Connecticut from 1997 to 2001. The overall case fatality rate was 16 percent. Over two-thirds of the patients were premature, and separate mortality data were not presented for preterm and term infants. Of the 132 *E. coli* cases, 68 were due to an ampicillin resistant species. It is difficult to ascertain the overall mortality in term and late preterm infants with neonatal sepsis, because there is a subset of septic patients who do not have positive culture results.⁷⁴

SUMMARY

Neonatal infection is a high incidence high-risk disease in India. Accurate diagnosis is difficult because of low sensitivity to even blood culture and other adjunctive indirect tests. Hence, the clinicians must accept the fact that a number of neonates will be started with antibiotic treatment even though they do not have the disease. In order to minimize the therapy for those who are not infected, a careful history, thorough clinical examination and a carefully performed sepsis screening can be used together in the management of neonatal sepsis. A variety of adjunctive therapy may offer potential benefits for neonatal sepsis. Most of the agents are not available and those that are available need further evaluation.

Intrauterine and Perinatal Infections—An Overview

Ajay Kumar, AK Dutta

Infections acquired *in utero* (Congenital) or in the perinatal period: During the birth process (Intarpartum) or in the postpartum period are significant causes of fetal and neonatal mortality (Table 1). The original concept of TORCH perinatal infections was to group five infections (T: Toxoplasmosis, O: Others usually syphilis, R: Rubella, C: Cytomegalovirus, H: Herpes simplex infection) with similar presentations. This term is now archaic and should not be used.¹ A new acronym is needed to include other

well described causes of *in utero* and perinatal infections like enteroviruses, Varicella zoster, Lyme disease and parvovirus. An inclusive term TORCHES CLAP has been suggested which stands for toxoplasmosis, rubella, cytomegalovirus, herpes simplex virus, enteroviruses, syphilis, chickenpox, Lyme disease and parvovirus. New pathogens are being discovered so it is unlikely that any acronym is going to be permanent.²

Table 1: Infections in intrauterine and perinatal period

Intrauterine viral infections

- Rubella
- Cytomegalovirus (CMV)
- Parvovirus B₁₉
- Varicella-Zoster (VZV)
- Enteroviruses
- HIV
- HTLV-1
- Hepatitis C
- Hepatitis B
- Lassa Fever
- Japanese Encephalitis

Perinatal and neonatal infections

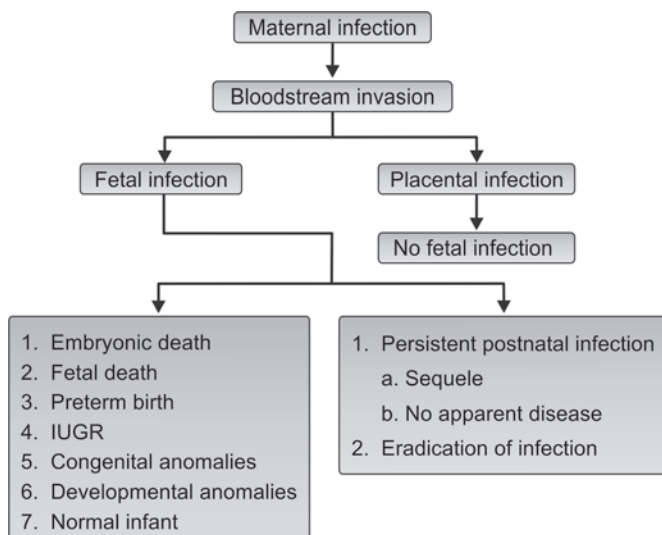

- Viral
 - Hepatitis B
 - HIV
 - HSV
 - Varicella (Chickenpox)
- Bacterial
 - Group B β strep
 - Gonorrhea
 - Chlamydia
 - Syphilis

PATHOGENESIS OF CONGENITAL AND PERINATAL INFECTIONS

The usual way in which the fetus is infected is by transplacental spread after maternal infection when the organism circulates in the mother's blood. These infections acquired *in utero* may be severe enough to cause fetal loss or can result in intrauterine growth restriction, prematurity or chronic postnatal infection. The degree of severity depends upon the gestational age of the fetus when infected, the severity of maternal disease and the virulence of the organism. The pathogenesis of these organisms is unique. They have very low virulence with the result the fetal infection rarely leads to death. Early in the pregnancy the most complex embryogenesis takes place, making the organs like eyes and ears vulnerable. The immature fetus lacks the immunologic mechanisms necessary to completely eliminate an infecting organism. Therefore, a state of immunologic tolerance is established with the result the organism persists in the fetus in the post natal period². (Flow chart 1)

CLINICAL MANIFESTATIONS OF CONGENITAL AND PERINATAL INFECTIONS

Hematogenous transplacental spread may result in death and resorption of embryo, abortion or stillbirth or live birth of a premature or term baby who may or may not be affected.

Flow chart 1: Pathogenesis of hematogenous transplacental infections

INTRAUTERINE GROWTH RETARDATION AND LOW BIRTH WEIGHT

Although low birth weight and small for date infants are associated with many maternal infections, evidence for a causal relationship is only sufficient for rubella VZV infection, toxoplasmosis and CMV infection. The organs of babies dying with congenital rubella syndrome³ or CMV infection contain a decreased number of morphologically normal cells.

DEVELOPMENTAL ANOMALIES AND TERATOGENESIS

CMV, rubella virus and VZV cause developmental anomalies in the human fetus. Coxsackie B3 and B4 are associated with congenital heart disease.²

CONGENITAL DISEASE

Clinical evidence of intrauterine infection may be present at birth or may manifest soon thereafter or years later. In infants with congenital rubella, toxoplasmosis, syphilis, congenital CMV, HSV or enterovirus infection signs of wide dissemination may be evident during the neonatal period. These include jaundice, hepatosplenomegaly and pneumonia. In some infants, the constellation of signs is sufficient to suggest the likely congenital infection (Table 2).

EFFICIENCY OF TRANSMISSION FROM MOTHER TO FETUS

The efficiency of transmission from infected mother to fetus varies among microbial agents and with the trimester

Table 2: Syndromes in neonates caused by congenital infections

Microorganism	Signs
Toxoplasma	Hydrocephalus, diffuse intracranial calcification, chorioretinitis
Rubella virus	Cardiac defects, sensorineural hearing loss, cataracts, microcephaly, blueberry muffin rash, hepatomegaly, interstitial pneumonia, myocarditis, disturbance in bone growth, intrauterine growth retardation
Cytomegalovirus	Microcephaly, periventricular calcification, jaundice, petechie or purpura, hepatosplenomegaly, IUGR
Herpes simplex	Skin vesicles or scarring. Eye scarring, microcephaly or hydranencephaly, keratoconjunctivitis, meningoencephalitis, sepsis with hepatic failure
Treponema pallidum	Bullous, macular or eczematous skin lesions involving palms and soles, rhinorrhea, dactylitis, osteochondritis, periostitis, hepatosplenomegaly and lymphadenopathy
Varicella zoster	Limb hypoplasia, cicatricial skin lesions, ocular abnormalities, cortical atrophy
Parvovirus B 19	Nonimmune hydrops fetalis
HIV	Severe thrush, failure to thrive, recurrent bacterial infection, calcification of the basal ganglia

of pregnancy. *In utero* transmission of rubella and toxoplasma occurs mainly with primary infection, whereas *in utero* transmission of CMV, HIV, and *T. pallidum* can occur in consecutive pregnancies.

The risk of congenital rubella infection in fetus of mothers with symptomatic rubella is 90 percent before 11 weeks of gestation, declines to a low of 25 percent at 23 to 26 weeks and then rises to 67 percent after 31 weeks. Infections in first 11 weeks of gestation are uniformly teratogenic, whereas no birth defect occurs in infants after 16 weeks of gestation⁴.

Frequency of stillbirth and congenital infection during pregnancy was least if the women acquired infection in first trimester (14%), increased in the second trimester (29%) and was highest in the third trimester (59%).⁵

Congenital CMV infection results from primary and recurrent infections. Whitley and Stagno estimated that 1 to 4 percent of women have primary infection during pregnancy, that 40 percent of these women transmit the infection to the fetus, and that 5 to 15 percent of the infants have signs of CMV disease. Congenital infection due to recurrent CMV infection occurs in 0.5 to 1 percent of live births, but less than 1 percent of the infected have clinically apparent congenital disease.^{6,7}

The fetal transmission rate of HIV infection from the infected mothers who received no treatment is about 25 percent. Data are insufficient to identify efficiency of transmission by trimester.⁸

DIAGNOSIS OF INFECTION IN THE PREGNANT WOMAN

Clinical Diagnosis

In many instances, the diagnosis of infection in pregnant women and congenital infection in the newborn can be suspected on the basis of clinical signs and symptoms. Many infectious diseases with serious consequences for the fetus are difficult to diagnose in the mother solely on clinical grounds. Asymptomatic or subclinical infection may be caused by rubella virus, CMV, *T. gondii*, *T. pallidum*, HSV and HIV. The vast majority of women infected during pregnancy with these organisms have no apparent signs of disease. Only 50 percent of women infected with rubella have a rash. Only few proportions of cases of CMV mononucleosis are recognized in pregnancy. Similarly, the number of women with clinical toxoplasmosis is less than 10 percent. The genital lesions associated with HSV infection and syphilis are often not recognized.²

ISOLATION AND IDENTIFICATION OF INFECTIOUS AGENT

The most direct mode of diagnosis is isolation of the microbial agent from tissues and body fluids such as blood, CSF, or urine. Amniotic fluid contains viruses or bacteria shed from the placenta, skin, urine, or tracheal fluid of the infected fetus. This fluid can be obtained earlier during pregnancy and can be used to detect the infecting organism by culture, antigen detection test, or PCR assay. These methods have contributed significantly to the diagnosis of rubella, VZV, CMV, and *T. gondii*.²

Serologic Diagnosis

The serologic diagnosis of infection in pregnant women most often requires demonstration of a significant rise in antibody titers against the suspected agent. If done in early pregnancy, a negative test will tell that women are unprotected against *T. pallidum*, *T. gondii*, and rubella. A positive test will tell that the woman is infected with hepatitis B or HIV. Difficulties in interpretation of serologic test results seldom arise when patients are seen shortly after exposure or at the onset of symptoms. Demonstration of IgA and IgE antibodies is useful in the early diagnosis of infection in the pregnant woman, fetus, and newborn.²

TORCH Screen

The utility of TORCH titres as an effective diagnostic tool has been questioned in the last decade because of overuse

and consistent lack of interpretability and reliability.⁹ Both maternal IgG and IgM antibody titers are performed routinely because IgG frequently persists once patients have been exposed to the pathogen. However, IgM also can be present for prolonged periods, three months to more than one year in acute toxoplasmosis¹⁰ which can create difficulties in interpreting potential fetal exposure during a pregnancy. In contrast to maternal serum, the presence of IgM antibodies in the newborn is more suggestive of congenital infection because these antibodies cannot cross the placenta, although contamination can occur at the time of delivery.

One study examined the cost and number of diagnoses of TORCH infections in 75 infants with intrauterine growth restriction who were screened with TORCH titres, urine cultures for CMV and head ultrasound.¹¹ Three infants had a probable infection diagnosed, one by a positive CMV urine culture and two by ultrasound of the head; none of the infants had a positive IgM antibody for toxoplasmosis, rubella, CMV, or HSV. The costs of the tests for the 75 infants were estimated at \$17,816 for IgM titers, \$5734 for CMV urine cultures, and \$28,165 for head ultrasound. The authors concluded that workup for TORCH infections were not cost-effective in the population of infants with intrauterine growth restriction. A study evaluating maternal TORCH testing found that complete maternal TORCH testing is often unnecessary and concluded that only testing for CMV would be cost effective.¹²

PREVENTION AND MANAGEMENT OF INFECTION IN PREGNANT WOMEN

Prevention of Infection

Pregnant women should avoid contact with persons with communicable diseases, particularly if women are known to be seronegative (e.g. CMV) or have no prior history of the disease (e.g. VZV). Precautions should be taken by pregnant woman if her partner has vesicles of HSV or suspected to be infected with HIV. Pregnant women should avoid eating undercooked lamb, pork or beef. They should avoid contact with cat feces.

Immunization

Routine immunization schedules for infants and children with currently available live vaccines, including measles, poliomyelitis, mumps and rubella should give lifelong protection.

Immunoglobulin

Human immune globulin after exposure to rubella, varicella, measles, or hepatitis A virus may modify clinical signs and symptoms of the disease but has not proved to be consistently effective in preventing disease and viremia in susceptible person. Human serum immune globulin is

of undetermined value in protecting the fetus of a susceptible woman against infection with these viruses. It may be used for rubella for women to whom therapeutic abortion is unacceptable.

Antimicrobial Therapy

Almost without exception, antimicrobial agents administered systemically to the mother pass to the fetus. Pregnant women with recently acquired acute toxoplasmosis, Lyme disease and syphilis should undergo treatment. Women who are colonized with *C. trachomatis* or group B *Streptococcus* may receive treatment under selected circumstances.²

INDIVIDUAL INFECTIONS

Toxoplasmosis

Toxoplasma gondii is a ubiquitous protozoan parasite that infects animals and humans. It is an intracellular parasite with a unique biphasic cycle that consists of a sexual cycle that occurs in felines and asexual cycle that occurs in other animals and humans. The infant is infected transplacentally after the parasite invades the placenta. The risk of transmission to the fetus during an acute maternal infection varies depending upon the gestational age during which the maternal infection occurred. As the gestational age increases, the risk of infection in the fetus increases but the severity of infection decreases. Once acquired, the latent encysted organism will persist for life in the host. Estimates of prevalence of congenital toxoplasmosis based upon serologic screening of neonates or infants range from approximately 1 per 1000 in some areas of Latin America to 1 per 10000 live births in US.¹³

*Congenital toxoplasmosis has four types of clinical manifestations.*¹³⁻¹⁵

- **Subclinical infection:** Most have no clinical manifestations (70 to 90%) on routine physical examination. More specific testing like CSF examination (mononuclear pleocytosis and raised protein), ophthalmic evaluation (macular scar) and CNS imaging (focal cerebral calcification) may reveal abnormalities.
- **Severe disease in neonatal period:** Clinical findings noted are chorioretinitis, abnormal CSF examination, seizures, intracranial infections, jaundice, splenomegaly, hepatomegaly, pneumonitis, hydrocephalus (Fig. 1) and rash.
- **Mild or severe disease in the first month of life:** Chorioretinitis, motor and cerebellar dysfunction, microcephaly, seizures, sensorineural hearing loss, mental retardation.
- **Sequel or relapse of undiagnosed infection later in the infancy, childhood or adolescence.**

The diagnosis of congenital *Toxoplasma* infection in newborn is usually made serologically. Diagnosis in newborn

Fig. 1: CT Scan head of a newborn with Congenital Toxoplasmosis showing dilatation of lateral ventricles with intracerebral and periventricular calcifications

relies on the presence of *Toxoplasma* specific IgM detected by ELISA or ISAGA. When the infant's IgM are negative or equivocal IgA and IgE ELISA should be performed.^{16,17} Detection of these antibodies is more sensitive than measuring IgM but specificity is not assured.^{18,19}

*Laboratory methods that involve isolation or demonstration of *T. gondii* include:*²⁰

- **Polymerase chain reaction:** PCR on amniotic fluid is particularly diagnostic of fetal infection. PCR can also be used for CSF, vitreous fluid, urine, peripheral blood, bronchoalveolar lavage fluid, cord blood or placenta.
- **Observation of cysts in placenta**
- **Isolation of parasite from blood or body fluid by mouse inoculation or tissue culture.**

Antenatal screening allows early diagnosis of acute maternal, fetal and neonatal infections and improves outcome. Routine screening throughout pregnancy is performed in France.²¹

Treatment:²¹ Spiramycin is recommended before 18 weeks gestation and until term if the fetus is uninfected by 18 weeks amniotic fluid PCR. This macrolide antibiotic reduces or delays vertical transmission to fetus through high placental levels. However, if transmission occurs disease severity may be unaltered. Pyrimethamine, sulfadiazine and folic acid are recommended for confirmed fetal infections after 18 weeks gestation or when unable to perform amniocentesis and all acute maternal infections after 24 weeks. Fetal infection diagnosed before 17 weeks should be treated with sulfadiazine alone until after the first trimester as pyrimethamine may affect organogenesis.

Therapy is recommended for all neonatal infections regardless of symptoms. As current medications do not eradicate *T. gondii* and primarily act against the tachyzoite form not tissue cysts extended therapy until 1 year of age

is recommended. Pyramethamine and sulfadiazine in combination are recommended till one year of age. Prednisolone is used for active CNS disease or active chorioretinitis, which threatens vision.

CONGENITAL SYPHILIS

It results from transplacental passage of *T. pallidum*. The risk of transmission to the fetus correlates largely with the duration of maternal infection, the more recent the maternal infection, the more likely the transmission to the fetus will occur. During the primary and secondary stages of maternal syphilis the risk of transmission to fetus approaches 100 percent. This risk declines to 10 to 30 percent in mother with late latent syphilis. Transmission through placenta can occur throughout pregnancy.²² The most important risk factors for congenital syphilis are lack of prenatal health care and maternal illicit drug use. Clinical scenarios that contribute to the occurrence of congenital syphilis include lack of prenatal care; no serologic test for syphilis (STS) performed during pregnancy; a negative STS in the first trimester, without repeat test later in pregnancy; a negative maternal STS around the time of delivery in a woman who was recently infected with syphilis but had not converted her STS yet; laboratory error in reporting STS results; delay in treatment of a pregnant woman identified as having syphilis and failure of treatment in an infected pregnant woman.²²

Case Definition

The center for disease control and prevention has given a case definition for congenital syphilis²³ (Table 3).

Clinical Features

Early congenital syphilis: It is arbitrarily defined by the clinical manifestations with onset before 2 years of age.²⁴ Two-third of live-born neonates with congenital syphilis are asymptomatic at birth.^{24,25} Clinical manifestations in untreated neonate appear by 3 months of age. The placenta of these neonates at birth may be large, thick and pale. The umbilical cord is edematous and shows spiral stripes of red and light blue discoloration. It may show the evidence of necrotizing funisitis.²⁶ The newborn may have hepatomegaly, rhinitis (snuffles), red or pink spots on back, buttocks, posterior thighs and soles. The rash progresses to desquamation and crusting. Other manifestations of congenital syphilis include nonimmune hydrops, myocarditis, pneumonia, pseudoparalysis of parrot (failure to move an extremity secondary to pain), nephritic syndrome and CNS involvement.²⁷

Late congenital Syphilis: It is arbitrarily defined by clinical manifestations with onset after two years of age. It develops in approximately 40 percent of infants born to women with untreated syphilis during pregnancy. Manifestations

Table 3: US Centers for disease control and prevention (CDC) surveillance case definition for congenital syphilis

Laboratory criteria for diagnosis

Demonstration of treponema palladium by dark field microscopy, fluorescent antibody, or other specific stains in specimens from lesions, placenta, umbilical cord, or autopsy material

Case classification

Probable

Infant whose mother had untreated or inadequately treated syphilis at delivery, regardless of signs in the infant, or

Infant or child who has a reactive treponemal test for syphilis and any one of the following:

Any evidence of congenital syphilis on physical examination:

- For children 0 to 2 years: Hepatosplenomegaly, rash, condyloma lata, snuffles, jaundice, pseudoparalysis, edema
- For children >2 years: Interstitial keratitis, sensorineural hearing loss, 'saber shins', frontal bossing, Hutchinsonian teeth, mulberry molars, mulberry molars, saddle nose, rhagades, Clutton joints

– Any evidence of congenital syphilis on radiographs of long bones

– A reactive cerebrospinal fluid (CSF) venereal research laboratory (VDRL) Test

– An elevated CSF cell count or protein (without other cause)

Confirmed

Case that is laboratory confirmed

include facial features (saddle nose, short maxilla, protuberant mandible), interstitial keratitis, sensorineural hearing loss, Hutchinsonian teeth (hypoplastic notched widely spaced teeth most commonly central incisors), mulberry molars (maldevelopment of cusps of first molars) and perforation of hard palate. Other manifestations include rhagades (perioral fissures or clusters of scars radiating around the mouth), anterior bowing of the shins (saber shins), enlargement of sternoclavicular portion of the clavicle (Higouminakis sign), painless arthritis of knees (Clutton's joints).²⁷

Diagnosis

It can be made by direct visualization of *T. pallidum* by dark field microscopy or fluorescent antibody staining of infected body fluids or lesions, placenta or umbilical cord.²⁸ Serologic tests can establish a diagnosis of proven/highly probable, at risk or unlikely congenital syphilis. Serologic tests include nontreponemal tests (e.g. Venereal disease research laboratory [VDRL] or rapid plasma reagin [RPR]) and treponemal tests (e.g. microhemagglutination test for *T. pallidum* [MHA-TP] or fluorescent treponemal antibody absorption [FTA-ABS]). Serologic tests for IgG antibodies are problematic because it is not possible to differentiate between passively acquired maternal antibody

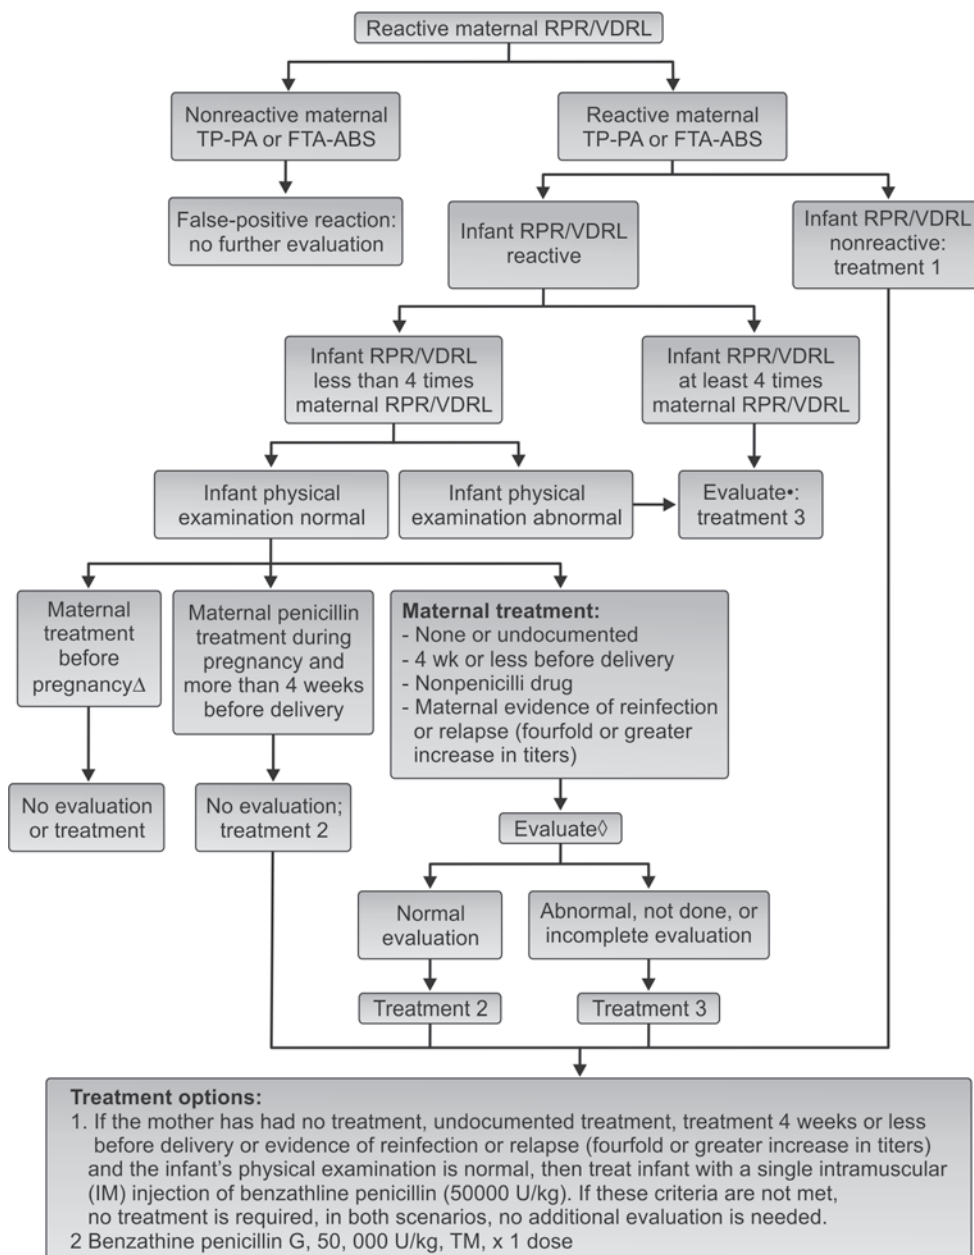

and endogenous antibody produced by the fetus/neonate. The ability to detect IgM antibodies, which do not cross the placenta would confirm fetal infection. Unfortunately, a sufficiently sensitive and specific IgM assay is not currently available for routine use in the assessment of congenital syphilis.²⁹

Maternal treatment history, clinical findings and interpretation of serological tests help to classify the neonate into following broad groups:²³ Flow chart 2.

Proven or Highly Probable Congenital Syphilis

Congenital syphilis is proven or highly probable if the neonate (<1 month of age) has any of the following: An abnormal physical examination that is consistent with congenital syphilis, a serum quantitative nontreponemal serologic titre that is \geq fourfold the corresponding maternal titre, a positive dark field or fluorescent antibody test of lesions, body fluid(s), placenta, or umbilical cord, a reactive serum VDRL/RPR and abnormal CSF, reactive treponemal antibody test after 15 months of age.

Flow chart 2: Congenital syphilis: Evaluation and management

Presumed Congenital Syphilis

Infants <1 month of age who have a normal physical examination and serum VDRL or RPR titres <fourfold the maternal titre are presumed to have congenital syphilis if their mother was not treated or received inadequate/suboptimal therapy.

At Risk for Congenital Syphilis

Infants <1 month of age who have a normal physical examination and serum VDRL or RPR titres <fourfold the maternal titre are at risk for congenital syphilis, even if their mothers were adequately treated.

Unlikely Congenital Syphilis

A diagnosis of congenital syphilis is unlikely if the infant has a normal physical examination and nonreactive VDRL/RPR and the mother was adequately treated during pregnancy and had an appropriate serologic response.

Treatment

Parenteral penicillin is the drug of choice for the treatment of congenital syphilis.³⁰ Penicillin is the only drug with documented efficacy and it has minimal toxicity. Effective treatment of syphilis requires maintenance of a minimal inhibitory concentration (MIC) of 0.03 units/ml of penicillin in serum (or cerebrospinal fluid) for 7 to 10 days. Current regimens are designed to achieve and maintain several times the necessary MIC and to avoid penicillin free intervals during therapy.

PARVOVIRUS INFECTION

Parvovirus transmission results after contact with respiratory secretions, blood/ blood products, or by vertical transmission. The prevalence of infection increases throughout childhood, such that approximately one-half of women of childbearing age are immune and the other half are susceptible to primary infection.³¹ B₁₉ infection during pregnancy can result in fetal complications including miscarriage, intrauterine fetal death and/or nonimmune hydrops fetalis.³² Because of this potential, it is critical to determine the serologic status of the pregnant woman who has a history of significant exposure to the virus or who has any of the classic symptoms of B₁₉ infection.

Pathogenesis

The fetus is especially susceptible to the effects of B₁₉-induced anemia due to its shortened RBC half-life and the expanding RBC volume. The relatively immature fetal immune system is also less able to effectively control virus infection. The ensuing fetal hydrops appears to result from the onset of severe anemia, which in turn causes high output heart failure. Fetal B₁₉ infection can also present with thrombocytopenia.

Diagnosis

Maternal parvovirus infection—IgM antibody capture radioimmunoassay and enzyme-linked immunosorbent assay (ELISA) are sensitive tests, detecting between 80 and 90 percent of patients with clinical B₁₉ infection.³³ Fetal parvovirus infection — Polymerase chain reaction (PCR) is a sensitive method to detect small amounts of B₁₉ DNA. Use of this technique on amniotic fluid is the method of choice to make the fetal diagnosis. Another option is to obtain fetal blood for B₁₉ IgM; however, percutaneous fetal blood sampling, the method used to obtain fetal blood, carries a 1 percent fetal loss rate.³⁴

Treatment

Mild to moderate anemia generally is well tolerated by the fetus and resolves without sequelae. Severe anemia, although uncommon, can lead to hydrops fetalis and death. Because parvovirus-induced anemia is a transient process, determination of fetal hemoglobin is not necessary unless severe anemia is suggested by sonographic signs, such as fetal skin edema, ascites or pleural or pericardial effusions. Doppler assessment of the fetal middle cerebral artery (MCA) peak systolic velocity (PSV) is emerging as an accurate tool for the determination of fetal anemia and is a noninvasive alternative to cord blood sampling.³⁵

When severe anemia is suspected because of an elevated Doppler MCA PSV or signs of hydrops, the fetus requires close monitoring and assessment of fetal hematocrit by percutaneous umbilical vein sampling. Intrauterine fetal blood transfusion usually is performed if severe anemia is confirmed.³⁶ Intravenous immune globulin (IVIG) has been used to treat acute parvovirus in immunodeficient adults and HIV-infected children. However, there is only one case report on its use as a fetal therapy.³⁷ Given the limited available data, the use of IVIG during pregnancy currently is not recommended.

Whenever possible, the management of a woman with a hydropic infant should be undertaken in a tertiary care facility staffed by individuals experienced in the care of sick neonates. As with all high-risk births, delivery of a hydropic infant mandates coordinated efforts by the obstetrician, perinatologist, and neonatal team to optimize pregnancy outcome.

The majority of hydropic infants require respiratory assistance and mechanical ventilation. Ventilation may be compromised by pulmonary hypoplasia, pulmonary edema, air leaks, or by the accumulation of pleural or peritoneal fluid. Abdominal paracentesis and thoracentesis of fetal ascites and pleural effusions may be needed either just prior to delivery or immediately after to facilitate resuscitation. Postnatal management depends upon the gestational age of the infant, other associated conditions (e.g. respiratory distress syndrome) and illness severity.

Infants with severe anemia and cardiovascular instability may benefit from an isovolumetric or partial exchange transfusion with packed red blood cells.

Prevention

Three groups of pregnant women potentially at risk of fetal parvovirus disease are those exposed to an infected household contact, schoolteachers and health care providers. Their status as acutely infected or susceptible can be determined by testing for serum IgG, IgM and PCR. For susceptible or acutely infected women, serial fetal ultrasonography should be done to monitor fetal growth and the possible evolution of hydrops. Serial determinations of maternal serum α -fetoprotein (AFP) may be done (AFP may rise up to 4 weeks before ultrasonography evidence of fetal hydrops), although this use is questioned.³¹

VARICELLA ZOSTER INFECTION

Varicella-zoster virus (VZV) is the virus responsible for varicella (chickenpox) and herpes zoster ("shingles"). VZV is a member of the herpesvirus family.

Congenital Varicella

Most cases of congenital varicella syndrome occur in infants whose mothers were infected between 8 and 20 weeks gestation. However, the overall risk of infection is quite small compared to numerous other viruses acquired during pregnancy. The risk appears to be approximately 2 percent if the infection occurs before 20 weeks.³⁸ Characteristic findings of affected infants include:³⁹

- Cicatricial skin lesions, which may be depressed and pigmented in a dermatomal distribution.
- Ocular defects, such as cataracts, chorioretinitis, Horner syndrome, microphthalmos and nystagmus.
- Limb abnormalities, which often include hypoplasia of bone and muscle.
- Central nervous system abnormalities, such as cortical atrophy, seizures, and intellectual disability (mental retardation).

Neonatal Varicella

It is a serious illness associated with a mortality rate up to 25 percent. Newborns born to mothers who are exposed to VZV or have clinical disease manifestations within two weeks of delivery are at the greatest risk for infection. The risk of infection and the case fatality rate are significantly increased when symptoms of maternal infection occur less than five days prior to delivery.⁴⁰ This interval allows insufficient time for the development of maternal IgG and passive transfer of antibody protection to the fetus. Postnatally acquired varicella that occurs between 10 and 28 days after birth usually is mild. (Fig. 2) However,

Fig. 2: Clinical photograph of neonate with varicella
(For color version see plate 1)

because of their relative immunologic immaturity, newborns are at greater risk for acquiring severe disease than are older infants or children.⁴¹

Prevention

The Advisory Committee on Immunization Practices (ACIP)⁴² recommends administration of VZIG/ VariZIG to newborns

- Whose mothers have signs and symptoms of varicella around the time of delivery (five days before or two days after)
- Premature infants born at >28 weeks of gestation who are exposed during the neonatal period and whose mothers do not have signs of immunity
- Premature infants born at <28 weeks of gestation or who weigh <1000 grams at birth and were exposed during the neonatal period, regardless of maternal history of varicella or vaccination. VariZIG should be administered within 96 hours because its efficacy after this time interval is not known.

Treatment

Acyclovir reduces the risk of mortality in severe varicella.⁴³ Newborns with severe infection should be treated with acyclovir (30 mg/kg per day in 3 divided doses IV) for 10 days. To be effective, antiviral treatment must be started as soon as possible after the onset of symptoms because most viral replication has stopped by 72 hours after appearance of the rash.

CONGENITAL RUBELLA

Congenital rubella infection (CRI) encompasses all outcomes associated with intrauterine rubella infection (e.g. miscarriage, stillbirth, combinations of birth defects, asymptomatic infection) whereas congenital rubella syndrome refers to variable constellations of birth defects (e.g. hearing impairment, congenital heart defects, cataracts/congenital glaucoma, pigmentary retinopathy).⁴⁴

Maternal-fetal transmission of rubella virus occurs via hematogenous spread during maternal viremia, which usually occurs five to seven days after maternal inoculation. After infecting the placenta, the virus spreads through the vascular system of the developing fetus. There are two proposed mechanisms for rubella cytopathology: Virus-induced inhibition of cell division⁴⁵ and direct cytopathic effects.⁴⁶

Clinical Features

Congenital rubella infection (CRI) may lead to fetal death *in utero*, premature delivery or congenital defects. CRI is a chronic infection and has a broad spectrum of clinical manifestations that may manifest throughout life. In neonates the manifestations of congenital rubella infection include IUGR, meningoencephalitis, hearing loss, cloudy cornea (Fig. 3), interstitial pneumonia, cardiac defects, hepatosplenomegaly, jaundice, hepatitis, radiolucent bone lesions (Fig. 4), petechiae and blueberry muffin lesions (Fig. 5), adenopathy, hemolytic anemia and

thrombocytopenia.⁴⁷ Delayed manifestations of rubella occur in about 20 percent of children with symptomatic congenital rubella infection. These manifestations include hearing loss, endocrine disorders (diabetes, hypothyroidism and growth hormone deficiency), eye problems

Fig. 4: Moth eaten appearance of bones in a neonate with congenital rubella

Fig. 3: Cloudy cornea due to glaucoma in a neonate with congenital rubella syndrome (For color version see plate 1)

Fig. 5: Clinical photograph of a newborn with congenital rubella showing blue berry muffin rash (For color version see plate 1)

(retinopathy, cataract, glaucoma), vascular effects (renal artery stenosis, hypertension), progressive panencephalitis and immune defects.⁴⁸

After fetal infection rubella virus persists throughout gestation and for months postnatally. At one year of age as many as 20 percent of infants with CRS shed virus in the pharynx.⁴⁹

Diagnosis

The presence of certain defects or laboratory data consistent with CRS satisfies the Centres for Disease Control and Prevention's clinical case definition (Table 4). Cases of CRS are classified as “suspected,” “probable,” “confirmed,” or “infection only,” depending upon clinical findings and laboratory criteria for diagnosis.⁵⁰

Table 4: Case definition and classification criteria for congenital rubella syndrome (CRS)

Clinical case definition

An illness, usually manifesting in infancy, resulting from rubella infection *in utero* and characterized by signs or symptoms from the following categories:

Category A: Cataracts/congenital glaucoma, congenital heart disease (most commonly patent ductus arteriosus or peripheral pulmonary artery stenosis), hearing impairment, pigmentary retinopathy

Category B: Purpura, hepatosplenomegaly, jaundice, microcephaly, developmental delay, meningoencephalitis, radiolucent bone disease

Laboratory criteria (any one of the following)

Isolation of rubella

Demonstration of rubella-specific immunoglobulin M (IgM)

Infant rubella antibody level (immunoglobulin G, IgG) that persists at a higher level and for a longer time than expected from passive transfer of maternal antibody (i.e. rubella titer that does not drop at the expected rate of a twofold dilution per month)

Polymerase chain reaction (PCR) positive for rubella virus

Classification Criteria

Suspected	A case with some compatible clinical findings but not meeting the criteria for a probable case A case that is not laboratory confirmed and that has either: – Any two complications from category A above, or
Probable	– One complication from category A and one from category B above and Lacks evidence of any other etiology
Confirmed	A clinically consistent case that is laboratory confirmed
Infection only Δ	A case that demonstrates laboratory evidence of infection but without any clinical symptoms or signs

Lab Diagnosis

Although the diagnosis of CRS is suspected clinically, it is confirmed with laboratory tests. Lab evaluation should be performed before the child reaches one year of age after which it is difficult to establish a diagnosis of congenital rubella infection.⁵¹ The confirmation can be done through isolation of rubella virus and serology.⁵⁰

Virus Isolation

Rubella virus is most frequently isolated from nasopharyngeal secretions, although it can also be cultured from blood (including cord blood), placenta, urine and cerebrospinal fluid.

Serology

Serologic confirmation of CRS consists of demonstration of rubella-specific IgM antibody or infant IgG rubella antibody level that persists at a higher level and for a longer time than expected from passive transfer of maternal antibody.

Management

Supportive care and surveillance and are the cornerstones of management for congenital rubella syndrome (CRS). At the time of diagnosis, a comprehensive evaluation should be performed to determine the extent of disease severity. The evaluation should include thorough neurologic, cardiac, ophthalmologic and audiologic examination; complete blood count; long-bone radiographs; and usually examination of cerebrospinal fluid. Acute management involves provision of supportive care and treatment of the clinical manifestations as necessary. Long-term management involves continued support and interventions for complications (e.g. sensorineural hearing loss, cataracts, cardiac defects) and monitoring for progression or late manifestations (e.g. hearing loss, endocrine problems).⁵²

CYTOMEGALOVIRUS INFECTION

Cytomegalovirus (CMV) is a ubiquitous virus that commonly infects people across the spectrum of all ages, races, and ethnic groups and those from a variety of socioeconomic, cultural and geographic backgrounds.⁵³

Congenital

Approximately 1 percent (0.2 to 2.5%) of newborns are born congenitally infected with CMV. Most of these newborns appear normal and are asymptomatic but 5 to 15 percent of congenitally infected newborns will have symptoms at birth. Both maternal primary and recurrent infection during pregnancy can result in congenital infection of the infant but the rate of transmission is far higher for mothers with primary infection (40 versus <1% transmission). Infants born congenitally infected with CMV as a

result of a primary maternal infection also are much more likely to have symptoms at birth and suffer sequelae.⁵⁴

Perinatal

Infants may be perinatally infected with CMV via contact with maternal cervicovaginal secretions during delivery or from breast milk ingestion after delivery. Preterm infants appear to be at greatest risk of acquiring the virus from breast milk.

Clinical Features

As many as 90 percent of newborns who are congenitally infected with CMV are asymptomatic at birth. However, as many as 15 percent of these apparently unaffected children can experience progressive hearing loss that most often is unilateral but occasionally may be bilateral.⁵⁵ Approximately 10 percent of congenitally infected newborns will have symptoms at birth. Somatic manifestations include: small size for gestational age, hepatosplenomegaly, petechiae and purpura of the skin and jaundice at birth.⁵⁶ At least two-thirds of the newborns with symptomatic congenital CMV infection will have neurologic involvement, including microcephaly, seizures, abnormal neurologic examination and feeding difficulties may be seen.⁵⁷

Although often asymptomatic, perinatal infection with CMV can produce a variety of clinical symptoms. A sepsis-like syndrome occurs most commonly and is associated with hepatosplenomegaly, abnormal blood counts with lymphopenia, neutropenia and thrombocytopenia, abnormal transaminases and pneumonitis.⁵⁸

Diagnosis

The diagnosis of congenital CMV infection or disease is accomplished by isolation of the virus in urine or saliva samples collected within the first three weeks of life. Detection of CMV DNA in the urine and serum of newborns also using polymerase chain reaction (PCR) techniques may be used to diagnose congenital CMV infection but these methods are less available, more expensive, and often less reliable than is traditional cell culture.⁵⁹ Prenatal diagnosis by viral culture or DNA detection of the virus in amniotic fluid or by CMV IgM antibody determination of fetal blood also has been reported and may be especially useful in the symptomatic fetus.⁶⁰ Serology for CMV IgG antibody determination (TORCH titers) is not helpful because most of the general population has CMV antibody and a positive result may only reflect passive transfer of maternal antibody to the infant. The presence of CMV IgM antibody in the newborn suggests congenital infection may be present. However, confirmatory viral culture still must be performed because both false-positive and false-negative serologic results occur.⁶¹

Treatment of neonates with congenital or perinatal CMV disease remains controversial but may be considered

in certain patients. Newborns who are likely to benefit immediately from antiviral therapy with ganciclovir include those with viral sepsis-like syndrome caused by CMV pneumonitis or severe and refractile thrombocytopenia, sight-threatening retinitis.⁶² Newborns who may benefit long-term from antiviral therapy include those with sensorineural hearing loss and microcephaly.

One report of a randomized clinical trial of ganciclovir (6 mg/kg per dose administered intravenously for six weeks) in newborns with severe congenital CMV disease and neurologic involvement showed apparent protection against hearing loss or progression of the infection and improved head circumference growth for the first 6 to 12 months of life.⁶³ Valganciclovir, an orally available form of ganciclovir, also has been used in the treatment of congenital CMV infection but data are not yet available for its use in infancy.⁶⁴

HERPES SIMPLEX

The incidence of neonatal HSV infection is estimated to be between 1 in 3000 and 1 in 20,000 births.¹ Neonatal HSV has three distinct periods of acquisition: Intrauterine, perinatal and postnatal.⁶⁵

Intrauterine

Occurs rarely (estimated incidence of 1 in 250,000 deliveries).

Perinatal

The majority (85%) of neonatal HSV infections are acquired perinatally. HSV is acquired perinatally when HSV infection, either symptomatic or asymptomatic, is present in the genital tract of the pregnant woman at the time of delivery. Factors that may influence perinatal transmission include the type of maternal HSV infection (primary versus recurrent), maternal HSV antibody status, duration of ruptured membranes, use of fetal scalp monitors and mode of delivery (cesarean versus vaginal).⁶⁶ However, most neonates with HSV disease are born to mothers without a history of HSV infection or other identifiable risk factors.⁶⁷

Postnatal

Approximately 10 percent of neonatal HSV infections are acquired postnatally.⁶⁶ Postnatal acquisition of neonatal HSV occurs when a caretaker with active HSV infection, such as herpes labialis, has close contact with the newborn infant.

Neonatal HSV

Can be broadly classified into three categories for therapeutic and prognostic considerations.

Fig. 6: Clinical photograph showing cluster of vesicles in a child with congenital herpes infection (*For color version see plate 1*)

Skin, Eye and Mouth

Vesicles typically appear on the sixth to ninth day of neonatal life. A cluster of vesicles often develops on the presenting part of the body, where extended direct contact with virus may occur (Fig. 6). Vesicles occur in 90 percent of infants with localized mucocutaneous infection and recurrent disease is common. Furthermore, significant morbidity can occur in these infants despite the absence of signs of disseminated disease at the time of diagnosis; up to 10 percent of infants later show neurologic impairment and infants with keratoconjunctivitis can develop chorioretinitis, cataracts and retinopathy.¹

CNS Disease

Approximately, one-third of neonates with HSV present with encephalitis in the absence of disseminated disease, and from 40 to 60 percent of these infants do not have mucocutaneous vesicles. These infants usually become symptomatic at 10 to 14 days of life with lethargy, seizures, temperature instability, and hypotonia. Mortality is approximately 15 percent with treatment and approximately two-thirds of surviving infants have impaired neurodevelopment.¹

Disseminated Infection

This is the most severe form of neonatal HSV infection. It accounts for approximately 22 percent of all infants with neonatal HSV infection. Symptoms usually begin within the first week of neonatal life. Clinical findings include seizures, shock, respiratory distress, disseminated intravascular coagulation (DIC), and pneumonitis. A typical vesicular rash may be absent in as many as 20 percent of infants. Mortality is around 57 percent. Forty percent of the infants who survive have morbidity.¹

Diagnosis

Viral Culture

Isolation of HSV by viral cell culture is the definitive laboratory method of establishing the presence of an active HSV infection in the neonate. Isolation of HSV from surface sites of the neonate, such as skin lesions, eye or conjunctivae, mouth or oropharyngeal secretions and stool or rectum, is significant particularly if obtained 24 to 36 hours after birth. Neonates with disseminated disease may have HSV isolated from their blood. Neonates with HSV hepatitis or necrotizing enterocolitis may have HSV isolated from duodenal aspirates, ascites fluid, or liver tissue. HSV may be isolated from tracheal aspirates in neonates with HSV pneumonia and isolation of HSV from the CSF or brain tissue is diagnostic of CNS involvement.⁶⁸

PCR Testing can be done on CSF, blood and amniotic fluid. The detection of HSV DNA in the cerebrospinal fluid (CSF) of a neonate confirms the diagnosis of central nervous system (CNS) involvement. CSF HSV PCR is more sensitive than viral culture.⁶⁹ In neonates with severe sepsis syndrome associated with disseminated intravascular coagulation, hepatitis or thrombocytopenia, the presence of HSV DNA in the blood or plasma confirms the diagnosis of disseminated neonatal HSV disease and provides the opportunity for early initiation of antiviral therapy.⁷⁰

DFA and EIA permit rapid detection of HSV antigens in skin and mucous membrane lesions.^{71,72} DFA has high specificity for HSV infection and typing of the HSV antigens may be done directly on material on the slide. However, DFA is not as sensitive as culture in many patients and accuracy depends on obtaining an adequate specimen containing cells from scrapings of the base of mucocutaneous lesions. EIA is primarily used to screen asymptomatic or pregnant women for HSV genital infection. Both false positive and false negative results may occur and combination with cell culture is recommended to optimize accuracy. The performance of rapid EIA in the diagnosis of neonatal HSV infection is not well established, highlighting the need for cell culture to confirm the diagnosis of HSV in neonates.⁷²

Serology

Combined HSV 1 and 2 serology is of little value, because many women are infected with HSV 1. Obtaining type-specific antibody from the mother or the infant may help determine whether there was maternal exposure to either and prognosis. Additionally, specific IgM may not be detected for up to 3 weeks in neonates. However, the number of different viral antigen-specific antibodies produced seems to correlate with the extent of disseminated disease, and the presence of certain antigen-specific antibodies may have long-term prognostic value.

Treatment

Acyclovir

Recommendations include treating infants with disease limited to the skin, eye and mouth disease with 20 mg acyclovir/kg every 8 hours for 14 days and those with CNS or disseminated disease for at least 21 days or longer if the CSF PCR remains positive. Infants with ocular involvement should have an ophthalmologic evaluation and consider topical ophthalmic agents (1% trifluridine, 0.1% iododeoxyuridine, or 3% vidarabine) in addition to parenteral therapy.¹

Prevention

The principal problem in developing strategies for the prevention of HSV transmission is the inability to identify maternal shedding of virus at the time of delivery. Viral identification requires isolation in tissue culture, so any attempt to identify women who may be shedding HSV at delivery would require antenatal cervical cultures. Until more rapid techniques such as a screening PCR are made available for the identification of HSV, the only clear recommendation that can be made is to deliver infants by cesarean section if genital lesions are present at the start of labor. The efficacy of this approach may diminish when membranes are ruptured beyond 4 hours. Nevertheless, it is generally recommended that cesarean section be considered even with membrane rupture of longer durations, although data showing efficacy beyond 4 hours are lacking. Infants inadvertently delivered vaginally in the setting of cervical lesions should be isolated from other infants in the nursery, and cultures should be obtained from the oropharynx/nasopharynx and conjunctivae. If the mother can be identified as having recurrent infection, the resultant neonatal infection rate is low and parents should be instructed to consult their pediatrician when a rash or other clinical changes (lethargy, tachypnea, poor feeding) develop. Weekly pediatric follow-up during the first month is recommended. Infants with a positive culture from any site or the evolution of clinical symptomatology should immediately have cultures repeated and antiviral therapy started. If caesarean delivery is performed after 24 hr or baby is vaginally delivered Acyclovir may be initiated without waiting for culture or DFA results.¹

ADVANCES IN CONGENITAL/PERINATAL INFECTIONS

During the past 20 years, a number of scientific and sociological changes have altered the scope of TORCH infections. Incidence of these diseases has changed significantly because there are better preventive measures available for diseases like Rubella and Varicella. The use of new therapeutic drugs has altered the picture of CMV and toxoplasmosis. Ganciclovir is showing promise as a drug to prevent

those with severe CMV infection from developing the progressive deafness and other sequelae that characterize the disorder. Blood products are now routinely tested for the virus and the use of seronegative blood permits the infection to be avoided in premature infants. Treatment for toxoplasmosis *in utero* and during the first year of life has been shown to significantly improve outcomes.

Advances in molecular diagnostics have enabled the development of faster, more precise methods to detect the presence of pathogens. DNA probes and PCR are able to identify pathogens when cultures and serologic tests are slow, difficult or inconclusive. Toxoplasmosis, for example, can be quickly detected in the amniotic fluid, allowing for earlier treatment of the fetus. Finally, the growing use of the Internet to access information has changed how health professionals educate themselves and the public. Websites that make available authoritative information and practical advice exist for a number of congenital infections and can be invaluable to parents.⁷³

CONCLUSION

The nature of TORCH infections has changed dramatically as a result of new vaccines, new pathogens, more sophisticated diagnostic testing and greater public awareness of the need for early prenatal care. In the future, we will have new organisms to consider, new vaccines to prevent these diseases and more effective treatments. The impact of the “new genetics” may enable the identification of those at risk for these infections even before conception.

Necrotizing Enterocolitis

Sanjay Wazir, Manish Balde

Necrotizing enterocolitis (NEC) is one of the most common gastrointestinal emergencies in newborn infants. In NEC, the small (most often distal) and/or large bowel gets injured, develops intramural gas and may progress to frank necrosis with perforation. Although the disease was identified more than a century ago, Schmid and Quaiser were first to coin the term NEC and the first comprehensive description of the disease was given by Berdon and colleagues in the 1960s. Despite the progress made in neonatology in the last few decades, NEC still baffles neonatologists' world over with unproven pathogenesis and no definite management and preventive guidelines being agreed upon. Not only the disease is associated with increased mortality but morbidity in terms of bowel strictures, short gut syndromes and poor neurodevelopmental outcome is also high. With increasing survival of premature babies, the population at risk for NEC is increasing. Spontaneous intestinal perforation although earlier was classified as NEC is increasing being identified as a separate entity.

EPIDEMIOLOGY

Due to improved NICU practices, routine antenatal steroids and surfactant use, the survival of ELBW babies is increasing and hence the population at risk for NEC is also ever increasing. Term babies constitute 10 percent of all cases. In most series, the incidence of NEC is reported at 1 to 5 percent of NICU admission or 0.5 to 5 per 1000 livebirths. Both the incidence of necrotizing enterocolitis and its fatality rates increase in inverse proportion to birth weight and gestational age. In the published NICHD neonatal network cohort (1999–2001), about 7 percent of 11,072 VLBW infants developed proven necrotizing enterocolitis (\geq stage II), with about half undergoing surgery.¹ In this cohort, rates were inversely related to birth weight,

with necrotizing enterocolitis affecting 11.5 percent of infants weighing 401 to 750 g, 9 percent of infants 751 to 1000 g, 6 percent of 1001 g. Almost similar rates have been reported by Vermont Oxford Network and Canadian neonatal network. The rates have remained stable over time across most neonatal networks, the only exception being study by New South Wales and Australian Capital Territory Neonatal Intensive Care Unit Study group (NSW ACT NICUS) reporting a reduction in the incidence of NEC from 12 percent in 1986 to 1987 and 1992 to 1993 to 6 percent in 1998 to 1999 for all infants born in New South Wales² at 24 to 28 weeks' gestation and the researchers noted that this decline occurred despite increasing VLBW admissions and survivors at NICUs. Mortality and surgery rates remained stable. Although encouraging, this is the only large study to report a decline in the rate of the disease in VLBW preterm infants, although a smaller, single-center report from the United States also reported a decline in the incidence of NEC in infants with birth weights between 500 and 800 g. Mortality and surgery rates remained stable. National Neonatal Perinatal Database 2003 from India has indicated the risk of NEC to be 0.2 percent. This low incidence is because only 3.4 percent of the babies included in the database were less than 1500 g and ELBW babies constituted only 0.7 percent of the population.

There is no definite sex predilection for NEC but the mortality is more common in the male VLBW babies. Black infants are at greater risk of NEC primarily because of the increased prematurity rates in this population. This reported racial disparity in deaths from the disease remained significant even after controlling for birth weight and other characteristics, and needs further investigation. There is no racial data in Indian population.

Mortality rates in NEC range from 15 to 30 percent. Although most cases of necrotizing enterocolitis are

managed medically, an estimated one-third of the infants undergo surgery. Mortality in surgical cases approaches 50 percent and is highest for the smallest, least mature infants. Most cases of necrotizing enterocolitis are sporadic, with no clear seasonal distribution, but outbreaks do occur. Observations made during these epidemics suggest that they are infectious outbreaks. No one infectious agent has been linked to epidemic necrotizing enterocolitis.

The age of onset of NEC is directly related to the birth weight and gestation age. NEC is uncommon in term infants, in whom it usually appears within 2 to 5 days after birth. The average age of onset has been reported to be 20.2 days for babies born at less than 30 weeks' estimated gestational age (EGA), 13.8 days for babies born at 31 to 33 weeks' EGA, and 5.4 days for babies born after 34 weeks' gestation. In an Indian study reported from PGIMER Chandigarh India, age of presentation was 4.9 ± 4.8 days, however, the population consisted of more mature babies with mean weight 1667 ± 577 g and mean gestation age 33.2 ± 2.6 weeks.³

PATHOLOGY

The predominant anatomic lesion in NEC is coagulative or ischemic necrosis. Necrosis is the direct result of ischemia. The usual site for NEC occurrence is the ileocolic region and sometimes the terminal ileum is the only part of the intestine affected. Necrosis involves the small and the large intestine in about 50 percent of cases and is divided equally according to continuous or discontinuous involvement.

The inflammatory process in NEC starts in the venules. The location and extent of the affected areas (often multiple) are random, and they are not related to the arterial supply (Fig. 1). NEC is characterized by necrosis which is out of proportion to the degree of inflammation with micro abscesses and crypt abscesses being relatively uncommon. These findings are reverse of what one would expect to see in the infectious colitis. Pneumatosis intestinalis which is hallmark of the disease develops largely as a result of fermentation of intraluminal contents by the

bacteria. Gas bubbles which may be grossly visible in the intestinal wall are reported to involve the entire colon and are more common in the term infant than in premature infant.⁴ Perforation tends to occur at the junction between normal and necrotic bowel, but it can occur amidst the devitalized bowel and can occur at more than one spots.

Microscopic examination shows mucosal edema and hemorrhage representing coagulative necrosis with presence of acute and chronic inflammatory cells. Pneumatosis is located in the submucosal region and between muscle layers. Subserosal pneumatosis is not seen microscopically because the gas is evacuated before fixation can be accomplished. Thrombi are widespread but bacteria are scanty in the wall. In rapidly progressive lesions, necrotic lesions can be seen in other organs like liver, spleen, adrenals and kidneys. Reparative changes, including epithelial regeneration, granulation tissue, and fibrosis are common in recovering NEC. The development of scar tissue and fibrosis, if circumferential may progress to stricture formation. This development is especially common in distal colon and may present several months after the initial disease has resolved.⁵

RISK FACTORS AND PATHOPHYSIOLOGY

Despite extensive research, the disease still seems to be incompletely understood. Prematurity and feeding seem to be most consistent correlates of the disease. Classic triad of pathological events consists of: (1) Intestinal ischemia 2) Colonization by pathological bacteria (3) Protein substrate in the intestinal lumen (Flow chart 1). Presence of any two is sufficient enough to produce the disease. The other pathogenetic mechanisms for the disease include immaturity in neonatal vasculature, immune function, motility and barrier function (Flow chart 1). NEC is more likely to appear following quantitative extremes (i.e. severe ischemia, highly pathogenic flora, or marked excess of substrate) and develops only if a threshold of injury, sufficient to initiate intestinal necrosis, is exceeded. This may be the reason why most babies in NICU do not develop the disease.

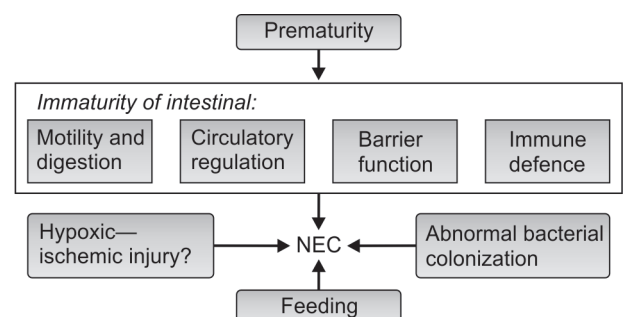

Fig. 1: Postmortem appearance of intestine in severe NEC with arrows indicating coagulative necrosis of whole of mucosa, submucosa, muscularis layer

Flow chart 1: Pathogenesis of NEC

Immature Intestinal Motility

Gut motility begins by second trimester but starts maturing by third trimester, although this can be hastened by early feeding. IUGR babies have less motility than the AGA babies and this could be partially responsible for the increased incidence in IUGR babies. In addition to impaired intestinal motility, premature infants have not yet developed the ability to digest and absorb nutrients, and incompletely digested molecules could contribute to intestinal injury. An intrinsic immaturity of the enteric nervous system delays transit and may lead to poor clearance of bacteria and subsequent bacterial overgrowth. Peristalsis also serves as an important component of epithelial barrier integrity. Peristalsis limits the amount of time during which antigens are able to interact with the apical surface of the enterocytes and also speeds the process by which antigen-antibody complexes are eliminated.⁶ Thus, impaired digestion of nutrients, coupled with delayed transit time, could result in injury of intestines with immature host and barrier defences.

Immature Intestinal Defence Mechanisms and Barrier Functions

Preterm babies have reduced amount of antimicrobial peptides defensins (α and β) and cathelicidins. These antimicrobial peptides have bioactivity against a wide range of microbes, including bacteria, viruses, fungi, protozoa, and spirochetes, and the immature intestine may be vulnerable to such pathogens.

Mucin produced by intestinal epithelial cells has many functions like lubrication, mechanical protection and protection against gastric and duodenal secretions. The level of mucin secreted increases with increase in the gestational age making these preterm babies more prone to intestinal inflammation. Developmental expression of mucin genes changes throughout the intestine and seems to mimic adult pattern expression between 23 and 27 weeks' gestation.

Intestinal epithelia are joined by tight junctional complexes, which form by 10 weeks' gestation. By selectively controlling the movement of small ions across the epithelial monolayer, enterocytes use Cl^- ions and water secretion (secretory diarrhea) to flush unwanted pathogens or toxins from the intestinal lumen. Since fetal intestinal secretion and absorption mature gradually, under the influence of amniotic fluid, from 26 weeks' gestation to full-term, pathogens might not be efficiently washed from the intestinal lumen in preterm infants.

Abnormal Bacterial Colonization

Since necrotizing enterocolitis does not occur in utero, intestinal bacteria might have a role in its pathogenesis, especially if abnormal colonization occurs. Pathogenic host-bacterial interactions have been well characterized—a

family of pattern recognition receptors (PRRs) transmits signals from microbial-associated molecular patterns (MAMPs) to induce proinflammatory and proapoptotic and antiapoptotic responses in host cells. Commensal bacteria can inhibit inflammatory pathways. Premature infants are especially susceptible to intestinal colonisation by pathological bacteria because of their daily exposure to nosocomial flora and the likelihood of exposure to antibiotics on admission to NICUs.

Immature Intestinal Circulatory Regulation

The occurrence of NEC in the setting of congenital heart disease, postbypass surgery or HIE in-term babies suggests a role for ischemia hypoxia model in the pathogenesis of NEC. The incidence of NEC is most common in the premature cyanotic heart disease and hypoplastic left heart syndrome. The most common suggested mechanism is the diving reflex where in the blood supply to the brain, heart and adrenals are maintained at the cost of blood supply to lesser vital organs like GIT.

Blood supply of the intestine in premature babies is dependent on balance between two main factors—ET-1 (endothelin) and NO (endogenous nitric oxide). ET-1 is a peptide mainly produced by endothelium and acts on the vasculature of intestine through two receptors—ETA and ETB. Activation of ETA receptors, which are predominantly located on vascular smooth muscle cells, leads to a profound and sustained contraction. Activation of ETB receptors located on endothelial cells leads to nitric oxide (NO)-mediated vasodilatation, whereas activation of ETB receptors located on vascular smooth muscle cells leads to vasoconstriction. Under basal conditions, ETA mediated vasoconstriction is more pronounced effect than ETB mediated vasodilatation. ET-1 is constitutively produced by its production can be increased by multitude of cytokines. ET-1 and its receptors are expressed in greater quantity in the premature babies as this peptide is strongly linked to angiogenesis in such subjects.

NO is produced during the enzymatic conversion of L-arginine to L-citrulline by a family of NO synthetases, including the endothelial isoform of nitric oxide synthase (eNOS) and is the primary vasodilating molecule for intestinal vasculature. Role of NO is gestation dependent with more vasodilatation occurring in response to the NO at lesser gestation. In newborn, under steady state, the balance favours vasodilatation due to an increased constitutive and stimulated production of NO. This serves to ensure an increased, therefore oxygen delivery, to the newborn intestine to meet the metabolic demands of early postnatal life. In pathologic states, endothelial dysfunction alters the balance favoring ET-1-mediated vasoconstriction and likely contributes to the compromise of blood supply of the gut.

In NEC, the balance of intestinal circulation is tilted in favor of vasoconstriction due to increased expression

of ET-1 in response to various cytokines like IL-1 β and reduced synthesis of NO due to reduced activity of eNOS.

L-arginine which is a precursor to the NO synthesis is found in lesser quantity in NEC. Supplementation with L-arginine has been found in experimental model of NEC to have lesser injury especially if started prophylactically than once the injury has occurred. In a double-blinded RCT, L-arginine supplementation to infants less than 28 weeks gestation significantly decreased the incidence of NEC.⁷ Possible mechanisms for benefit include increased NO production due to increased substrate availability and the fact that arginine is the precursor for the production of other amino acids such as glutamine and glutamate, both of which are important in maintaining physiologic intestinal processes. The finding that L-arginine supplementation decreases the incidence of NEC in premature human infants certainly warrants further study via a multicenter randomized controlled trial.

Growth Factors and Pathogenesis of NEC

Epidermal growth factor (EGF) acts on the enterocyte receptor (EGFR) which is primarily located on the basolateral surface of enterocytes resulting in trophic, maturational, and healing effects on intestinal mucosa. EGF increases with increasing gestational age. Maternal milk is source of EGF in the postnatal period. There is some experimental data suggesting that level of EGF expression is directly related to the development of NEC. Enteral supplementation with EGF before the injury significantly decreased the incidence and severity of experimental NEC. One of the postulated mechanisms for protective role of breast milk in NEC could be related to presence of EGF in breast milk as compared to the formula milk. Supplementation of EGF in experimental mouse model has been reported to decrease the incidence of NEC,⁸ downregulate the production of inflammatory cytokines, and decrease apoptosis at the site of injury. EGF is recently used by Sullivan and co-workers⁹ in a randomized, double-blind, prospective trial with recombinant EGF 1-48 (rEGF) in small group of premature neonates with evidence of NEC stages II or III. The investigators reported that repair of intestinal epithelium was seen at 4, 7, and 14 days as inferred by rectal biopsy specimens. Heparin-binding epidermal-like growth HB-EGF factor is a member of EGF family and uses the EGFR signaling pathway to stimulate cell growth and differentiation. Again in experimental models of NEC and neonatal shock syndrome, HB EGF has been shown to increase the proliferation of epithelial cells and increase in intestinal blood flow. G-CSF supports growth and proliferation of neutrophil precursors. GCSF receptors are present on nonhemopoietic tissue like gut in neonates as well. Amniotic fluid in utero and human milk in the postnatal period provide significant concentration of GCSF. Canpolat and co-workers¹⁰ administered enteral

G-CSF to preterm infants diagnosed with stage I NEC for 5 days. They reported prevention of disease progression with shorter time required for resolution of clinical symptoms, duration of therapy, and length of hospital stay when compared with controls. Presence of EPO in human milk suggests that this might also have some beneficial effect also this has not been extensively studied as of now.

RISK FACTORS AND PREVENTION OF NEC

Antenatal Steroids

The data regarding the antenatal steroids and incidence of NEC is conflicting. Cochrane systematic review on use of antenatal steroids shows an overall reduced incidence of NEC in addition to reduction in neonatal deaths. However, two large retrospective studies have shown increased risk of NEC with antenatal exposure possibly as a result of increased survival of babies with less pulmonary morbidity. Despite the possibility of an increased risk of NEC with the use of antenatal steroids, single course of antenatal corticosteroids to accelerate fetal lung maturation in women at risk of preterm birth is still recommended because of the effects on other outcomes.

Patent Ductus Arteriosus

Patent ductus has been implicated in the pathogenesis of NEC because of the diastolic steal of blood to the lungs. Prophylactic ligation of the PDA within 24 hours of birth results in decreased incidence of NEC. The effect of prophylactic treatment with indomethacin on NEC is variable. However, symptomatic treatment of PDA with indomethacin is associated with increased risk of NEC presumably secondary to decreased splanchnic blood flow.

Antibiotics for Premature Rupture of Membranes

Results of the ORACLE trial has suggested that use of amoxicillin is associated with increased risk of NEC and hence for PROM the antibiotic of choice should be erythromycin alone.¹¹

Maternal Cocaine Use

It has been associated with increased risk of NEC probably because of decrease of intestinal blood flow.

H₂ Blocker Use

In a large case control study from NICHD, use of H₂ blocker has been associated with increased risk of NEC.¹

Fluid Restriction

Excess fluid has been implicated in the pathogenesis of NEC. A systemic review and meta-analysis indicates that restricted water intake significantly increases postnatal weight loss and significantly reduces the risk of NEC.¹²

Blood Transfusion

Low quality evidence has shown an association between neonatal blood transfusion and the development of NEC.¹³ Withholding enteral feeds for a few hours during a blood transfusion may have theoretical benefits, but there is no published evidence to support this practice.

Oral Antibiotics

Because of the role of bacteria in the pathogenesis of NEC, oral antibiotics have been tried to prevent NEC. Meta-analysis¹⁴ has reported that the administration of prophylactic enteral antibiotics resulted in significant reduction in NEC without any impact on mortality. The possible harmful effects of prophylactic antibiotics including the development of bacterial resistance and alteration of the natural microflora make it difficult to recommend this strategy for prevention of NEC.

Oral Immunoglobulins

One of the mechanisms by which breast milk is protective for NEC is presence of immunoglobulins in the milk which inhibits the growth of pathogenic bacteria. IgA, being a secretory immunoglobulin, might be expected to be more efficacious in protecting the neonatal gastrointestinal tract than the more readily available IgG. A Cochrane review on the oral supplementation of immunoglobulins to prevent NEC involving three trials did not show any specific benefit.

Congenital Heart Disease

Among term babies congenital heart disease is an important risk factor for developing NEC. Factors associated with an elevated risk of NEC in infants with heart disease include premature birth, hypoplastic left heart syndrome (OR 3.8), truncus arteriosus (OR 6.3), and episodes of poor systemic perfusion or shock (OR 6.5).¹⁵ Heightened suspicion is warranted in newborns with these risk factors. Outcome of babies with NEC in CHD patients is better with decreased risk of perforation, need for a bowel operation, strictures, need for a stoma, sepsis, and short bowel syndrome compared with the noncongenital heart disease group.

Probiotics

When compared to term infants, VLBW infants at risk of NEC have abnormal fecal colonization, demonstrate a paucity of normal enteric bacterial species, and have delayed onset of bacterial colonization. Probiotic bacteria are live microbial supplements that colonize the gastrointestinal tract and potentially provide benefit to the host. Potential mechanisms by which probiotics may protect high risk infants from developing NEC and/or sepsis include increased barrier to migration bacteria and their products across the mucosa, competitive exclusion

of potential pathogens, modification of host response to microbial products, augmentation of IGA mucosal responses, enhancement of enteral nutrition that inhibit the growth of pathogens, and up-regulation of immune responses. A meta-analysis of 11 trials involving 2176 babies showed a 30 percent reduction in the incidence of NEC and there was also a reduction in the incidence of death amongst VLBW babies. No significant adverse effects were reported. Some authors have concluded that it is unethical to compare probiotics with placebo given the degree of benefit, however, further understanding of probiotics in terms of selection, dosing, duration, and short and long-term effects is needed to decide the optimum strain, dose etc.¹⁶

Prebiotics

Prebiotics are nondigestible dietary supplements, such as long chain carbohydrates or mucins, which promote proliferation of beneficial commensal bacteria. Preliminary studies show increased *Bifidobacterium* stool colonization and decreased pathogenic bacterial colonization in preterm infants fed with formula containing prebiotics besides having effect on host immune system. Because prebiotic supplements do not contain live microorganisms, they carry less risk of infection than probiotic therapies. However, prebiotic administration has been associated with unwanted (but reversible) side effects such as flatulence, bloating and diarrhea. At present there is no consensus on use of prebiotics for prevention of NEC.

Postbiotics

Prebiotics are bacterial metabolites such as butyric acid, a short-chain fatty acid produced by commensal bacteria in the colon through anaerobic catabolism of complex carbohydrates and acts as major energy source for colonic enterocytes and has an incompletely understood role in intestinal growth, inflammatory suppression, apoptosis. Butyrate has been administered with limited success in human inflammatory bowel disease, but there are as yet no studies in neonates.

Other experimental therapies include acidification of gastric pH by acidification of the diet, adding PUFA (which is a precursor to the vasodilatory and cytoprotective cytokines) to the diet of preterm babies. Erythropoietin treated preterm babies have been shown to be having lesser incidence of NEC as compared to the control group. EPO also acts as a trophic factor in the gut whether given enterally or parentally. These therapies although promising has to be clinically validated.

Feeding and NEC

Only 10 percent of the cases of NEC occur in nonfed babies and aggressive feeding regimens have been implicated in the pathogenesis of NEC. Different studies have

been performed regarding the feeding type, volume, rapidity of increase in feeds, etc. and NEC.

Feeding Volume and NEC

Two randomized, prospective trials including an Indian study have assessed infants with feeding volume increments of 30 mL/kg/d¹⁷ and 35 mL/kg/d¹⁸ compared with a control group whose feedings were increased by 15 mL/kg/d. Infants receiving the larger incremental volumes reached full feeding volumes earlier than the control infants without increasing the risk of NEC. Meta-analysis of the trials suggests that there is no increased risk of NEC with rapidly increasing feed increments. The confidence interval, however, is too wide suggesting that the proof is not entirely convincing, hence in ELBW babies, we tend not to increase more than 20 to 25 mL/kg/day.

These results are in conflict with those of Berseth and colleagues,¹⁹ who compared infants randomly assigned to daily increases in feeding volumes with infants whose feeds were held at a minimal volume for the first 10 feeding days. This study demonstrated a significant increase in NEC in the group with advancing volumes, and the study was closed early because the incidence of NEC was 10 percent in the advancing volume group versus 1.4 percent in the minimal volume group. The enteral feeds in the study were started only on day 10, which is not the routine practice across NICUs and hence, the study cannot be interpreted in light of current practices.

Method of Feeding

McGuire²⁰ performed a meta-analysis to compare transpyloric versus intragastric tube feedings. The incidence of NEC was similar between the two feeding methods among

the 8 studies evaluated, as were growth and time to establish full enteral feedings. Infants fed transpylorically experienced significantly higher mortality, and the authors concluded that the routine use of transpyloric tube feeding is not warranted, given the lack of evidence for benefit compared with the increased risk.

Donor Human Milk versus Formula

That breast milk is protective for NEC, whether the same benefit is extended by using donor human milk as compared to the formula milk is preterm babies has been analyzed in a meta-analysis of four trials²¹ which suggest that NEC is three times less likely to occur in the donor human milk group with NNT being.²⁰

Feeding after the Diagnosis of NEC

Conventional practice has been to delay introduction of feeds for a substantial time after the diagnosis by two recent reports have questioned the rationale. A recent study²² has looked at the feeding of babies with established NEC. These investigators reinitiated enteral feedings in infants when portal gas was absent for three consecutive days on abdominal radiographs. When compared with historical controls who were refeed 10 days after diagnosis, these study infants initiated feedings sooner (median 4 days, range 3 to 14 days) and reached full enteral feedings sooner (9 days vs 19 days; $P < 0.001$), had less catheter-related sepsis and shorter hospital stays. This data suggests that probably in some subsets of babies with NEC, feeds could be introduced earlier than is the current practice, precluding the need for TPN. A similar study in NEC Stage II cases showed that fasting for less than 5 days after diagnosis was associated with lesser catheter related sepsis

Table 1: Modified Bell's staging of NEC

Stage	Systemic signs	Intestinal signs	Radiographic signs
IA Suspected NEC	Temperature instability, apnea, bradycardia, lethargy	Gastric retention, abdominal distension, emesis, heme-positive stool	Normal or intestinal dilation, mild ileus
IB Suspected	Same as above	Grossly bloody stool	Same as above
IIA Definite, mildly ill	Same as above	Same as above, plus absent bowel sounds with or without abdominal tenderness	Intestinal dilation, ileus, pneumatosis intestinalis
IIB Definite, moderately ill	Same as above, plus mild metabolic acidosis and thrombocytopenia	Same as above, plus absent bowel sounds, definite tenderness, with or without abdominal cellulitis or right lower quadrant mass	Same as IIA, plus ascites
IIIA Advanced, severely ill, intact bowel	Same as IIB, plus hypotension, bradycardia, severe apnea, combined respiratory and metabolic acidosis, DIC, and neutropenia	Same as above, plus signs of peritonitis, marked tenderness, and abdominal distension	Same as IIA, plus ascites
IIIB Advanced, severely ill, perforated bowel	Same as IIIA	Same as IIIA	Same as above, plus pneumoperitoneum

than the control group (0 vs 29 percent) without increase in other complications.²³

CLINICAL FEATURES

Are extremely variable with generalized and local signs both being present. The severity of symptoms varies according to the progression of the disease. The onset of NEC can be sudden or insidious. In the sudden form, abrupt clinical deterioration occurs, which is indistinguishable from sepsis syndrome. Age at presentation is inversely related to gestational age at birth, with full term infants often presenting in the first few days of life. Median age at presentation is between 2 to 3 weeks of age. Neonates most commonly present with feeding intolerance, delayed gastric emptying, abdominal distension or tenderness (or both), occult or gross blood in the stool, lethargy, apnea, respiratory distress, or poor perfusion. Because early signs of this disease are nonspecific, sepsis may be suspected before necrotizing enterocolitis.

GI signs can include any or all of the following:

- Increased abdominal girth
- Visible intestinal loops
- Obvious abdominal distention and decreased bowel sounds
- Change in stool pattern
- Hematochezia
- A palpable abdominal mass
- Erythema of the abdominal wall.

Systemic signs can include any of the following:

- Respiratory failure
- Decreased peripheral perfusion
- Circulatory collapse
- With insidious onset, the clinical signs may be mild, whereas patients with fulminant disease can present with severe clinical abnormalities.

In 1978, Bell and colleagues proposed a system for the uniform clinical staging of infants with necrotizing enterocolitis. They classified infants as having stage I (suspect), stage II (definite), or stage III (advanced) disease. These criteria were subsequently modified by Walsh and Kliegman (Table 1). Guidelines for management of necrotizing enterocolitis are based on diagnosis according to these modified criteria.

Increased gastric aspirate are often considered a significant risk factor for the disease. However, the overlap amongst the values for the control and the study group is so huge that this cannot be used as a single marker for stopping feeds. Most of studies showing association of increased gastric residues to the development of NEC have shown increase occurred 1 to 3 days before the development of NEC and for the rest of the days the volume of aspirates was no different. The connotation to this is that in any baby who is otherwise well and has an increased gastric aspirate in first week of life should not be a reason for withholding feeds unless the aspirates are persistently

high. Increased abdominal girth of more than 2 cm is 66 percent sensitive antecedent to stage III NEC.²⁴

DIFFERENTIAL DIAGNOSIS

Sepsis with ileus, in both term and preterm patients, can mimic NEC. Both present with systemic signs of infection and abdominal distension. The absence of pneumatosis on plain radiographs argues against NEC, but does not rule it out but in any case the treatment for both conditions is essentially the same. In VLBW infants, inspissated meconium syndrome results in distended intestinal loops. However, these babies typically present with obstructive signs without evidence of sepsis. Isolated gastric perforation can result in pneumoperitoneum. Gastric perforation may be associated with administration of indomethacin or corticosteroids. Iatrogenic gastric perforation from feeding tubes occurs rarely. Although patients who have gastric perforation present with pneumoperitoneum, they are not as systemically ill as patients who have NEC. Patients who have Hirschsprung enterocolitis or severe gastroenteritis may present with pneumatosis.

DIAGNOSIS

Laboratory Diagnosis

Neutrophilia with or without left shift is seen in less severe NEC, with neutropenia observed more commonly in severe NEC and this is associated with poor prognosis. G-CSF use in patients with neutropenia and sepsis including NEC has shown improved survival in babies but the effect was not sustained when the meta-analysis excluded the nonrandomized trials.

Infants with severe NEC develop thrombocytopenia with incidence of 65 to 90 percent. Lower platelet counts have been reported to be associated with greater disease severity. In NEC, platelet counts may fall rapidly (within hours) a finding that supports consumption rather than decreased production and for this reason the therapeutic response to platelet transfusions is commonly short-lived. Indications for transfusion should be based on the presence of clinical bleeding, potential risks of bleeding, as well as the severity of thrombocytopenia. Worsening platelet count may be one indication for surgery.

Anemia is multifactorial in origin. Hemolytic anemia is common with NEC. Red blood cell morphology is consistent with thrombotic microangiopathy and includes teardrops, schistocytes, spherocytes, and acanthocytes. Hemolysis is related to T-cell crypt antigen activation which is seen in almost one-third of the patients. T-crypt antigen is a naturally occurring antigen found on human erythrocytes, normally concealed by a layer of N-acetylneuraminic acid, unless exposed by bacterial or other neuraminidases. When blood donors have antibodies to T crypt antigen, transfusing infants with T-crypt antigen activation may worsen the clinical course of NEC.

Hence, if possible one should ask blood bank for T-antigen negative blood. In addition to hemolysis, blood loss anemia is seen. Iatrogenic anemia may contribute to the problem, since frequent blood sampling is mandatory.

Coagulation abnormalities are common in NEC as the premature babies are endowed by lower levels of coagulation protein and with severe disease there are rapidly consumed and result in features suggestive of DIC. Treatment continues to be supportive, with administration of clotting factors.

Hypонатremia secondary to the tissue sequestration of sodium and third space fluid loss along with acidosis indicating decreased tissue perfusion are important hallmarks of the disease.

SEROLOGICAL TESTS

CRP a relatively sensitive but nonspecific marker for NEC and hence should not be used in isolation for diagnosis of NEC. Serial C-reactive protein could be useful in the management of the disease. Persistently high C-reactive protein indicated developing complications, such as stricture or abscess, or the need for surgical intervention.

Investigators have attempted to identify specific markers that would allow early diagnosis and treatment of NEC. Intestinal FABP are small (14 kDa) proteins that constitute up to 2 percent of the cytosolic protein of mature enterocytes and is raised in serum after any intestinal injury including NEC. Although seems promising, but the data currently is available from three studies including only 42 subjects and the specific cut off to differentiate NEC from other disease is not clear.

Imaging

The imaging modalities that are used in neonates during the active phase of NEC include plain abdominal radiography and abdominal sonography, other modalities like CT and MRI have not been found to be useful in clinical practice.

Plain Radiography

This is currently the modality of choice for diagnosis and staging of NEC. We recommend performing abdominal radiographs every 8 hours during the acute phase of suspected or diagnosed NEC beside anytime a clinical deterioration occurs. The interval can increase if the baby is showing signs of recovery. The plain radiograph should include two views—vertical beam with the patient supine and horizontal view with patient supine called the cross table view. Both vertical and horizontal beam views are required for follow-up in the first 48 hours following diagnosis, as the vast majority of perforations occur in this time frame. After this, vertical beam views alone may suffice unless there is specific concern for perforation. In normal neonates, gas is most often present through most

of the small and large bowel resulting in gas pattern called the “mosaic” appearance.

INTESTINAL DISTENSION

Bowel distension may be focal or generalized depending on the extent of the disease and is a result of ileus and partial obstruction. This sign is the earliest and may precede the development of clinical signs of NEC by few hours and the degree of dilatation usually correlates well with the clinical severity of the disease. Persistence of dilatation suggests failure of response to medical therapy or deterioration. An ominous sign is the change from generalized dilatation to an asymmetric distribution where dilatation is confined to a more localized area of the abdomen. It is even more worrisome if the asymmetric pattern persists and the dilated loops maintain the same appearance as fixed loops on follow-up plain abdominal radiographs. Prone and decubitus positions are helpful in differentiating a normal dilated intestine from an ischemic noncompliant segment. This suggests the development of full-thickness necrosis and may precede clinical deterioration including signs of peritonitis. For these reasons, the degree and pattern of bowel dilatation are the most important signs for early diagnosis and for follow-up. However, bowel distension is a very nonspecific sign.

Pneumatosis Intestinalis

Although not pathognomic, intramural gas is most commonly seen in NEC in premature infants. The incidence of intramural gas varies from 20 to 98 percent in various studies. Intramural gas is most commonly present in the distal small bowel and large intestine and hence it is most commonly seen in the lower right quadrant (Fig. 2), although it can affect any part of the gut. The amount of

Fig. 2: Soap bubbly pattern due to intramural gas in the right iliac fossa

intramural gas present does not always relate to the clinical severity of NEC and disappearance of intramural gas does not always correlate with clinical improvement.

Intramural gas may be diffuse or localized and appears as linear or cystic radiolucencies and represents an intramural hydrogen gas resulting from bacterial fermentation. The linear lucencies often appear curvilinear; they represent intramural gas in the subserosa and appear as black lines on the radiograph, which can occasionally be confused with overlapping bowel loops filled with gas. A clue to differentiating intramural gas from overlapping loops is the white lines that often accompany the black lines of intramural gas. The white lines represent the mucosa and submucosa, which are lifted off the serosa and are contrasted by the subserosal intramural gas and the intraluminal gas. A search for white lines rather than the black lines may often be more fruitful in helping one confirm the presence of intramural gas. Cystic form has a granular or foamy appearance and frequently is confused with fecal material. It represents gas in the submucosal layer of the bowel.

Portal Venous Gas

It is an extension of intramural gas that enters the veins of the bowel wall and passes into the portal venous system. This is reported to be present in 30 percent cases of confirmed NEC. It appears as branching, linear, radiolucent vessels (Fig. 3) that may extend from the region of the main portal vein toward the periphery of both hepatic lobes. Portal venous gas must be differentiated from gas in the biliary tree, which is uncommon in the neonatal period and is more centrally located in the larger ducts, in contrast to portal venous gas, which may extend more peripherally.

Diminishing Bowel Gas

Also described as asymmetric loops of intestine, which suggest an abnormal motility pattern. In the presence of

ischemia, the reported poor motility allows affected loops of bowel to be filled with fluid, resulting in diminished amount of visualized bowel gas compared with other areas of normal intestine where gas is propelled by peristaltic waves.

Free Abdominal Air

Free gas in the peritoneal cavity results from bowel perforation (Fig. 4), which most commonly occurs in the distal ileum and proximal colon. The view obtained with the horizontal beam is particularly useful for detecting small amounts of gas. On the cross-table lateral view, free gas may appear as triangular lucencies between loops of bowel anteriorly just beneath the abdominal wall or as small bubbles or linear gas collections anterior to the liver. On the supine view, large amounts of gas may give rise to the “football” sign, where the gas outlines the whole of the peritoneal cavity, the undersurface of the diaphragm, and the falciform ligament (the lacing of the football). Smaller amounts of free gas may give rise to lucency below the diaphragm without giving rise to the full-blown football sign. Even on the supine view, smaller amounts of free gas may be detected when both sides of the bowel wall are outlined (Rigler’s sign).

Ultrasonography

When to perform abdominal US during follow-up and how often has not been established. In those neonates who respond promptly to medical therapy, abdominal US probably has no role. However, it may play a significant role in two groups of patients. The first group includes those neonates in whom the evolution of changes at plain abdominal radiography is not in keeping with the clinical course, and the second group includes those who are deteriorating clinically but have no evidence of pneumoperitoneum at plain abdominal radiography.

Fig. 3: Portal venous gas

Fig. 4: Pneumoperitoneum

Abdominal US depicts intramural gas as hyperechoic foci in the bowel wall. Large amounts of intramural gas may give the wall a speckled or granular appearance, which can be confused with dense calcification. However, the latter usually has a much sharper posterior acoustic shadow than intramural gas. Portal venous gas may be seen in the main portal vein and its major branches as intraluminal echogenic foci moving with the blood flow. In the smaller intraparenchymal portal branches, portal venous gas is seen as hyperechoic foci that, when sufficient enough, form a linear, branching pattern. Free abdominal air would present as hyperechoic foci with dirty shadowing either between the anterior surface of the liver and the abdominal wall, between bowel loops, or floating on free peritoneal fluid just deep to the abdominal wall. Accumulation of free intraperitoneal fluid can be seen in neonates with more severe NEC with or without perforation and presence of low-level echoes or septations within the fluid is more suggestive of perforation, as they suggest the presence of pus or intestinal contents. Another major advantage of abdominal US is the ability of this modality to directly assess arterial perfusion of the bowel wall, as this is not possible with plain abdominal radiography which may help in determining the viability of the bowel. Kim et al²⁵ have suggested that monitoring with abdominal US may also be helpful in determining the most appropriate time to reinitiate and advance feeding, and it may also be

used to differentiate recurrent NEC from other causes of bowel distension.

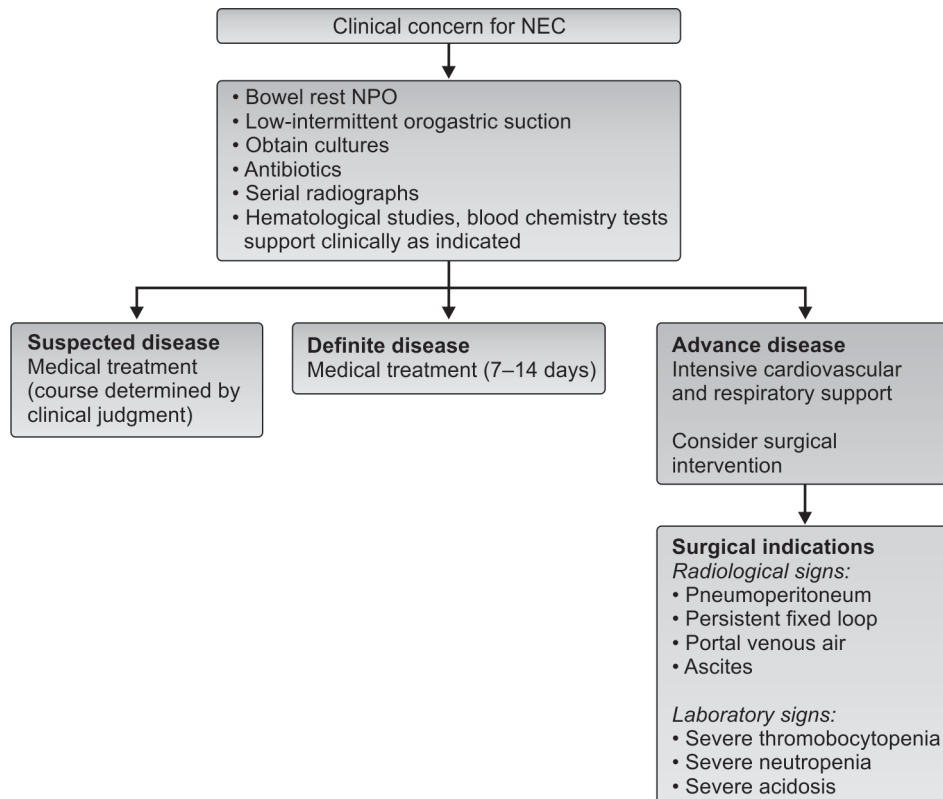

MANAGEMENT (FLOW CHART 2)

Medical Management

The goal of medical management is to stabilize the infant and prevent progression of an early form of NEC to the more advanced stage of the disease. When the diagnosis is suspected, stoppage of feeding and decompression of the gut by nasogastric suction (10–12F tube) is initiated. Nasogastric decompression is important to prevent reduction in intestinal blood flow. A complete blood count, serum electrolytes, and blood gases are obtained along with blood culture. Most require some mechanical ventilatory support. If necessary, tracheal intubation is preferred to continuous positive airway pressure to prevent aerophagia and subsequent greater bowel distention. Many patients will be hypovolemic and require fluid resuscitation and correction of acid base imbalance. If there is evidence of coagulopathy, administration of platelets, fresh-frozen plasma, or cryoprecipitate may be indicated. Inotropes may be required if circulation still is not improved despite fluid resuscitation.

Choice of antibiotic therapy may be guided by patterns of resistance in the individual unit. In addition, VLBW infants are at risk for bacteremia from coagulase-negative

Flow chart 2: Clinical decision making in NEC

Staphylococcus. Accordingly, empiric treatment with vancomycin and a third-generation cephalosporin is appropriate in some cases. Such babies are at increased risk of fungal sepsis because of broad spectrum antibiotic usage and PICC lines. Amphotericin, administered either empirically or following proven culture, may be necessary later in the course of treatment. Routine addition of clindamycin to the antibiotic regimen does not reduce the frequency of intestinal gangrene or perforation and may be associated with an increase in late stricture formation.²⁶ Anaerobic cover with metronidazole may be necessary in cases of perforation.

Close clinical and laboratory monitoring is essential in the management of patients with NEC. Serial physical examination including transillumination to detect pneumoperitoneum and frequent radiological examinations every 6 to 8 hours should be carried out along with blood gas and electrolyte estimations. Over next 24 to 48 hours, the disease may stabilize, improve or progress to advanced stages.

If the disease stabilizes, then most centers would not start feeding babies for 7/14 days after a stage II/III disease respectively, although this as discussed earlier has been questioned in two recent studies. When the feeding is resumed, it is reinstituted preferably with breast milk and advanced slowly. If there is any suspicion of recurrence of NEC after introducing oral feeds, a nasogastric tube is replaced and feeds restarted after a week of hyperalimentation. In case the baby still does not tolerate feeds, then an oral contrast study should be done to rule out the presence of stricture.

Surgical Treatment of NEC

The primary goal of surgical therapy is to improve the patient's condition after medical therapy has failed by removing ischemic and necrotic diseased intestine and/or the spilled intraperitoneal fluid and stool collections resulting from intestinal perforation. If the surgery is required to be done in NEC, then it is mostly required in first 5 days of the initial diagnosis.

Indication for considering surgical option includes:

- Pneumoperitoneum is considered as an absolute indication for surgery. However, sensitivity of pneumoperitoneum is 48 percent in detecting intestinal gangrene.
- Abdominal paracentesis is considered by some authors to be useful indicator for need for surgery. If the free flowing fluid tapped from the abdomen is brown or hemorrhagic with bacteria seen on gram stain, the tap is considered positive for gangrenous bowel, and surgery is indicated.
- Fixed mass on palpation indicating an intraperitoneal abscess or an aggregate of coalesced and infarcted loops of intestine. Apart from this other relative indication are fixed dilated loop on a radiograph, cellulitis of the abdominal wall.

- Worsening despite medical management indicates the intestinal ischemia is progressing to frank gangrene and forms a relative indication for operation.
- Portal venous gas as an indication for need for surgery is controversial.

Traditional surgical management of intestinal necrosis relies on the principles of controlling the source of peritoneal contamination by laparotomy, exploration of the intra-abdominal viscera, and excision of the involved, necrotic intestine. Generally, accepted principles in the operative management of perforated NEC have emerged from numerous institutional, retrospective reviews of surgically treated infants. These management guidelines include: (1) Aggressive perioperative resuscitation, often including inotropic support; (2) Expedient and minimal operative behavior with attempts at limiting physiologic insult; (3) Evaluation of the entire intestine with resection of only necrotic or perforated bowel; (4) Diverting enterostomy proximal to intestine of questionable viability; and (5) Preservation of the ileocecal valve if possible.

Surgical options include: (1) Laparotomy involving resection of the involved intestine with either a enterostomy formation or a primary anastomosis. An intermediate option is laparotomy with intestinal resection and delayed anastomosis 48 to 72 hours later; (2) Primary peritoneal drainage for perforated NEC may help to resuscitate and treat a critically ill infant.

Laparotomy and intestinal resection with enterostomy—is the procedure of choice for isolated perforations less than 20 cm in length. In perforated NEC however, there are multiple areas of necrosis with intervening viable bowel. In such situations, a proximal defunctioning enterostomy is done, which is closed electively later on. There is no agreement on time, weight or age at which an enterostomy should be closed. Major factors used to determine the timing of final surgery are time from original operation, stoma output and rate of the weight gain. In general, enterostomy is closed in 4 weeks to 4 months in otherwise thriving neonates.

Laparotomy and intestinal resection with enterostomy: Advantages of this method include avoidance of morbidity due to enterostomy complications, reduction of postoperative morbidity and a shorter hospital stay. The involved segments of intestine are excised and a primary anastomosis is performed, with routine lavage of the abdominal cavity. This method may be preferred in cases of multiple perforation where a much proximal enterostomy would lead to serious problems with fluid and electrolytes issues and failure to thrive. The major contraindications to resection and primary anastomosis are poor intestinal perfusion and residual macroscopic disease. Disadvantage of this technique is that sometimes the length of bowel resected may be larger than the damaged bowel.

Until resection with enterostomy versus primary anastomosis in perforated NEC is compared in a prospective,

randomized clinical trial, a definitive, evidence-based conclusion for procedure superiority cannot be made.

An intermediate option for physiologically unstable infants with perforated NEC is laparotomy with excision of involved intestine and delayed anastomosis 48 to 72 hours later. This “clip and drop-back” technique has been reported to be useful in selected infants with peritonitis associated with extensive intestinal necrosis and may be useful particularly in infants with proximal jejunal disease. Initial operative management goals are to excise necrotic intestine and preserve remaining viable intestine while preventing further contamination by placing either surgical clips or staples on the remaining bowel ends. Bowel continuity is restored 2 to 3 days later during a period of relative physiologic stability with delayed primary anastomosis using standard technique. This approach avoids the need for diverting enterostomy and its associated complications.

An alternative technique for extensive bowel involvement with multiple perforations called patch, drain and wait was developed by Moore. In this technique perforations are closed by transverse sutures, two transabdominal drains (Penrose) are placed and close observation and monitoring is employed, while providing TPN. A potential benefit is preservation of the bowel length, although multiple fistulas occur frequently, requiring additional surgery.

Peritoneal Drainage

It was first introduced in 1977 by Ein and involves placing one or two Penrose drains into the peritoneal cavity in the right and left lower quadrants under local anesthesia. Drains are removed over 7 to 10 days unless there still is meconium or purulent discharge. If no improvement occurs or the patient's clinical condition continues to deteriorate over 24 to 48 hours, a laparotomy should be performed.

Primary peritoneal drainage may be useful in the resuscitative phase of perforated NEC; urgent bedside reduction of abdominal distention by drainage reduces mean airway pressure and improves oxygenation index in critically ill neonates with NEC. This is contrary to established surgical principles in the management of intra-abdominal sepsis. Possible reasons why this procedure may be effective in small preterm babies may be premature infants have a limited ability to compartmentalize intra-abdominal infection; therefore, complete drainage of the abdominal cavity with a single drain may be effective. Additionally, models of fetal wound healing have demonstrated a lack of significant scar formation, and may account for intestinal remodeling and healing clinically observed with peritoneal drainage.

The advantages of primary peritoneal drainage include being relatively inexpensive, can be performed at the bedside, can be done under local anesthesia and

survivors can avoid morbidity associated with enterostomy. The disadvantages of this method include it is difficult to measure the severity of the disease, possibility of missing alternative diagnosis like volvulus which may present similarly and drainage may be ineffective in managing patients with circumferential necrosis as these patients would either develop a fecal fistula to the drain site or complete bowel obstruction. An Indian study had suggested that only those babies who are severely acidotic at presentation and in shock would need surgical laparotomy and rest can be managed by peritoneal drainage.²⁷

Comparison of peritoneal drainage with laparotomy in perforated NEC: There is no clear consensus on the optimal surgical management of premature infants with perforated NEC. Moss²⁸ and colleagues performed a meta-analysis of ten studies with 475 patients comparing primary peritoneal drainage versus laparotomy. There was no statistically significant survival advantage between primary peritoneal drainage versus laparotomy. Assignment of treatment group was biased substantially by gestational age and birth weight; the mean birth weight of infants subjected to primary peritoneal drainage was 931 g compared with 1615 g in the laparotomy group ($P = 0.0004$). Because of the difference in the population studied it is not possible to conclude whether primary peritoneal drainage or laparotomy offered better survival in infants with perforated NEC. We have to wait for the results of the multicenter trial by NICHD to get a clear answer on this subject.

OUTCOME AND COMPLICATIONS

Over the years, the survival of neonates with NEC has increased progressively and varies from 65 to 85 percent in different series. Mortality rate is dependent on birth weight and associated co-morbidities and severity of multiorgan failure present before the surgical intervention.

Postsurgical complications occur in approximately half of all the patients undergoing surgery for NEC. Immediate postoperative complications include stoma stenosis, retraction or prolapse, wound infection, and intra-abdominal abscess. Cholestasis can develop in such babies due to prolonged fasting and long-term parenteral nutrition. Recurrent NEC may occur in 4 to 6 percent of the bases. The antecedents to recurrence have not been fully described but 70 percent of patients with recurrence can be treated conservatively.

Long-term intestinal complications include strictures, malabsorption, short gut syndrome. Incidence of strictures varies from 10 to 36 percent and is more common after medical management than surgical. The most common site for stricture formation is colon (70%), with the most common colonic site being splenic flexure (20%). Multiple strictures are more common after surgical management. It is advisable to perform a contrast enema before contemplating closing an enterostomy. Malabsorption, may result

from decreased absorptive area, bacterial overgrowth, bile salt depletion (in case of ileal resection). Short gut syndrome is the most serious long-term complication and incidence is estimated at 20 percent.

NEURODEVELOPMENTAL OUTCOME AND NEC

VLBW baby survivors of NEC have a poor neurodevelopmental outcome as compared to VLBW babies without the NEC. In a recent meta-analysis on this topic involving 7843 children,²⁹ out of which of whom 821 had NEC. Neurodevelopmental impairment occurred in 45 percent of children who had had neonatal NEC, compared to 35 percent of children who had been VLBW or ELBW but did not have NEC, with an odds ratio of 1.58 (1.25 to 1.99). Overall the surgical NEC group was 2.34 times more likely to have neurodevelopmental impairment than the medical NEC group (95% CI 1.51 to 3.60, $p = 0.0001$). Factors causing poor neurodevelopment outcome in premature infants are complex. However, specifically related to NEC is the lack of adequate postnatal nutrition for the growth of brain and damage to existing cerebral tissue due to infection or inflammation, respiratory insufficiency, hypotension, acidosis, fluctuations in glycemic control, disseminated intravascular coagulation. In particular, infection and sepsis, which may result from intestinal perforation and/or gangrene, have been highlighted as independent risk factors. Surgery for NEC also causes a cytokine surge which could be responsible for white matter damage. Poor outcome may be independently associated with surgery, with or without NEC. Twenty-eight percent of surviving ELBW infants who required surgery of any sort had a poor sensorineural outcome.

Spontaneous Intestinal Perforation

It is an entity which is increasingly being identified in preterm population different from NEC. Incidence varies from 2 to 8 percent amongst the VLBW babies with male to female ratio being 3:1. This condition generally affects babies with gestational age less than 30 weeks or IUGR babies. When SIP does occur in the near-term or term infant, the defect usually appears in the colon, and the infant's prognosis is better. Five factors have been proposed as potential etiologies or risk factors for SIP:

- Altered GI tract perfusion or ischemia/hypoxia
- Thinning or absence of the intestinal muscularis, the smooth muscle layer of the intestinal wall
- The increased pressure transmitted to the GI tract by mechanical ventilation
- Specific medications, such as indomethacin and dexamethasone
- Infection with coagulase-negative *Staphylococcus* (CONS) or *Candida*.

Histological criteria for SIP include perforations of one or two locations that involve less than 5 cm of bowel. Patients with SIP have "muscular defects such as patchy

thinning or interruption of both the circular and longitudinal layers". In contrast, in NEC, the tissue shows ischemic damage and hemorrhage.

The onset of SIP is often insidious, and the patient is clinically stable. A blue-black discoloration of the abdominal wall is a common finding probably secondary to staining of the underlying tissues by meconium in the peritoneal fluid. Additional signs and symptoms of SIP include abdominal distention, delayed first stool after the third postnatal day, and leukocytosis. Many infants, however, present with no symptoms at all.

Peritoneal air or even a gasless abdomen on X-ray can be the first or only sign of intestinal perforation. Evidence of pneumatosis or portal venous air on X-ray is considered pathognomonic of NEC and not SIP. In the case of a gasless abdomen on X-ray, an abdominal ultrasound can be performed to confirm particulate matter outside the intestines. A gasless abdomen in a perforated patient may seem counterintuitive, but it is possible in a premature patient who may be intubated or have immature swallowing, which decreases the amount of air in the intestinal tract.

Two main treatments exist for intestinal perforation—peritoneal drainage and laparotomy with resection. Like in case of NEC, there is no consensus as to the most appropriate mode of intervention. Those who advocate laparotomy feel that an isolated stable perforation could progress to a more seriously compromised intestinal segment with significant clinical deterioration. Through early surgical intervention, they hope to avoid the potential for deterioration and the need for surgery when the patient is in a more compromised state. Those who advocate the initial peritoneal drainage feel most cases can recover without need for laparotomy and most clean perforations can seal on their own. As of now there are no RCTs to suggest that which method is better and choice and comfort of the operating surgeon and the facilities at the place of surgery should decide the best option.

SUMMARY

NEC is still an enigmatic disease for clinicians worldwide involved in the care of newborns. The incidence and the mortality due to this disease has not changed in last couple of decades. Pathogenetic mechanisms have to be better understood to be able to provide better treatment modalities. Epigenetic mechanisms if they exist also need to be understood as to why only few babies develop NEC and some may get away in the same environment. There is an urgent need to conduct trials to resolve many undecided issues in the management like which surgical option is the best. Close long-term neurodevelopmental follow up of patients treated for NEC is important and families of such patients should be consulted appropriately before surgery regarding the risk for neurological and developmental outcome.

Surgical Emergencies in the Neonate

Rajeev Kulshreshtha

Surgical emergencies in the neonates can be anticipated on routine antenatal maternal ultrasonography in large majority of the cases. Some of the important findings on maternal ultrasonography, which provide clue to the post-natal surgical emergencies are as follows:

- Polyhydramnios
The important lesions associated with polyhydramnios are:
 - Esophageal atresia.
 - Intestinal obstruction.
 - Abdominal wall defects.
 - Congenital diaphragmatic hernia.
- Oligohydramnios
 - Renal dysgenesis or agenesis (Potter's disease).
These babies have associated pulmonary hypoplasia which leads to postnatal respiratory distress.
- Meconium ascites.
- Free floating bowel loops in amniotic fluid, indicates abdominal wall defects.
- Large head is suggestive of hydrocephalus.
- Absence of the fusion of the vertebral arches indicating spina bifida.
- Distended bladder and upper urinary tracts is suggestive of posterior urethral valves.
- *Fetal ascites*: It is usually associated with posterior urethral valves.
- Large mass in the sacral region of the fetus indicating sacrococcygeal teratoma. Important postnatal surgical emergencies in a neonate can be broadly grouped as follows:
 - Respiratory distress
 - Gastrointestinal tract lesions
 - Large skin defects
 - a. On the back:
 - i. Spina bifida

- b. On the front
 - i. Omphalocele
 - ii. Gastroschisis
 - iii. Exostrophy bladder
- Retention of urine: Posterior urethral valves
- Acute scrotum
 - i. Torsion testes
 - ii. Strangulated inguinal hernia

RESPIRATORY DISTRESS

Presenting Features

Presenting features of respiratory distress in a neonate are as follows:

- Restlessness in an otherwise asymptomatic baby.
- Tachycardia: Heart rate more than 160/mt.
- Tachypnea: Respiratory rate more than 60/mt.
- Tachypnea associated with subcostal/intercostals recession.
- Color change from normal pink to dusky and later cyanosis.
- Grunting, apnea or gasping respiration: The presence of these indicates very serious situation.
- Associated signs are apex beat shifted to right, scaphoid abdomen, excessive salivation or frothing at mouth or nostrils or abdominal distention.

Respiratory distress is evaluated as follows:

- Clinical sign and symptoms of respiratory distress.
- Blood chemistry: Hematocrit, blood sugar, serum calcium and blood gas analysis.
- X-ray chest upright view including abdomen.

The respiratory distress can be graded as minor, moderate and severe depending on clinical sign, symptoms and investigations. Tachypnea associated with subcostal and intercostal recession is considered as moderate. Tachypnea associated with grunting, color changes or

Table 1: Pediatric Respiratory Distress Scoring System

Score	0	1	2
Respiratory			
Rate (Per Minute)	< 60	60–80	> 80
Cyanosis	Absent	Not present with 40% oxygen	Present with 40% oxygen
Subcostal recession	Absent	Mild	Moderate
Grunting	Absent	Audible with stethoscope	Audible without stethoscope
Air entry	Clear	Decreased	Absent

apnea is considered as severe. Alternatively respiratory distress scoring may be used. (Table 1) Each sign is given a score. Score 6 to 8 is considered as severe distress.

If respiratory distress is minor, then history and investigations are done to confirm the diagnosis and plan appropriate management. If the distress is moderate or severe first respiratory distress is managed as follows: History and investigations are done after resuscitation.

General Management of Respiratory Distress

- Neonate is placed under radiant warmer or incubator, without clothes for close observation. Body temperature is maintained. Hypothermia and hypoxia precipitates metabolic acidosis.
- Minimum handling of the baby, so as to reduce oxygen requirements. Increased handling results in increased basal metabolic rate with increased oxygen demands.
- Gentle oropharyngeal suction with pressure of 10 cm of water is done. Patent airway is maintained.
- Humidified oxygen (40%) is given in oxygen hood. Oxygen is never given by face-mask or nasal catheter in a neonate. PaO_2 is maintained between 60 to 80 mm Hg.
- Oral feeds are stopped. Intravenous fluids and antibiotics are started.
- Nasogastric tube is passed. It decompresses stomach thus decreases abdominal distention resulting in reduced splinting of the diaphragm, which facilitates respiration. NG tube prevents vomiting, which avoids aspiration of gastric contents.
- Baby maybe kept in prone, head low position. This position reduces apnea, shortens gastric emptying, and prevents aspiration. However, if baby requires resuscitation then supine position is preferred.
- Blood gas studies, serum calcium, blood sugar and hematocrit is done and repeated at regular intervals.
- Vital signs including respiratory and cardiac status is monitored very carefully.
- If ventilatory support is required, it should not be delayed.

Management of some important surgical conditions causing respiratory distress is as follows:

CHOANAL ATRESIA

Congenital blockage of posterior nares is termed as choanal atresia. It maybe uni or bilateral. Blockage maybe due to membrane or by bone. Bilateral choanal atresia presents with respiratory distress.

Up to the age of 3 to 4 months, baby is compulsive nose breather. In bilateral choanal atresia if mouth is closed or baby is feeding, respiratory distress starts and the baby may become cyanotic. Either the baby cries or if an airway is put in the mouth, distress disappears dramatically.

Bilateral choanal atresia is a rare anomaly. The incidence is 1 in 60,000 live births.

Diagnosis is confirmed by:

- Inability to pass 6 F red rubber catheter through nose into oropharynx.
- Radiopaque dye is instilled in the nostril. A lateral X-ray of the face is taken. Presence of dye in nostrils only and absence of dye in the oropharynx confirms the diagnosis.

Treatment is as follows:

- Initially airway in the oral cavity is effective.
- If the blockage is membranous, it is ruptured through nostrils.
- If the blockage is bony, it is removed via transpalatal route.

ESOPHAGEAL ATRESIA

Congenital discontinuity of esophageal lumen is known as esophageal atresia. This maybe with or without fistulous communication with trachea.

Incidence of esophageal atresia varies from 1 in 2500 to 1 in 4500 in live births. Both the sexes are equally affected.

Antenatal Diagnosis

Antenatally esophageal atresia is diagnosed on routine maternal ultrasonography, which reveals polyhydramnios associated with inability to detect fetal stomach. High resolution scan can identify distended upper atretic esophageal pouch with repeated swallowing and regurgitation efforts.

Classification

Esophageal atresia is classified in the following types:

- Type I.* Esophageal atresia with no tracheal communication (8–10%).
- Type II.* Esophageal atresia and proximal esophageal pouch communicating with trachea.
- Type III.* Esophageal atresia and distal esophageal pouch communicating with trachea, which is usually at the carina. This is the most common type (87–90%).

- Type IV.* Esophageal atresia and both proximal and distal pouches of esophagus communicates with trachea.
- Type V.* No esophageal atresia, but esophagus communicating with trachea.
It is also called as H Type fistula (1–2%).
- Type VI.* There is only esophageal stenosis and no fistulous communication with trachea.

Diagnosis

At Birth

In view of the antenatal diagnosis on maternal ultrasonography, the diagnosis is confirmed at birth by passing, a sterile 6 to 8 F red rubber catheter orally. If it gets arrested at 10 cm from gum margin, it indicates the diagnosis of esophageal atresia, which is confirmed by X-ray chest combined with abdomen, in an erect posture with catheter *in situ*.

- If the catheter lies in the upper pouch and there is no abdominal gas shadow, it indicates esophageal atresia, Type I (Fig. 1)
- If catheter lies in upper esophageal pouch with distended stomach and abdominal gas shadows, it indicates esophageal atresia, Type III (Fig. 2).

After Birth: Presenting Features

If antenatal maternal ultrasonography is not done and diagnosis is not established by passing the catheter immediately after birth, the late presenting features are:

- Excessive salivary secretions and frothing at nose and mouth.
- Signs and symptoms of respiratory distress due to aspiration pneumonia, followed by apneic attacks and cyanosis.
- On giving oral feeds, there is acute episode of coughing, choking, and cyanosis.

Associated Anomalies

Infants with esophageal atresia have a 48 to 55 percent incidence of associated anomalies. The coexisting anomalies are highest in the group of esophageal atresia without tracheoesophageal fistula.

(Type I, 58%) The most common associated anomalies are cardiac (40%) and of the genitourinary tract.

Preoperative Management

The surgical correction of esophageal atresia is done after full resuscitation, and never as an emergency procedure. The specific management includes:

- Proximal esophageal pouch is decompressed by continuous slow suction. Double lumen Replogle catheter is best suited for this purpose. This is necessary to avoid accumulation of secretions in upper pouch, which may lead to aspiration pneumonia. In between intermittent suction is also done.
- Baby is nursed in prone or lateral horizontal position, which permits easy access for suction and monitoring the vital signs of the baby.
- Appropriate investigations are done to confirm the diagnosis and to detect associated anomalies.

Fig. 1: Plain X-ray of chest and abdomen: Type I esophageal atresia

Fig. 2: Plain X-ray of abdomen and chest: Type III esophageal atresia

Timing of Surgical Correction

Immediate Primary Repair

The indications are:

- No pulmonary complications, viz. severe pneumonia.
- An arterial PaO_2 more than 60 mm Hg in room air.
- Not associated with major congenital malformations which are incompatible with life.
- Distance between proximal and distal esophageal pouch less than 2.5 cm.

Delayed Surgical Intervention

The indications are:

- Associated with pneumonia, sepsis or complex cardiac malformation.
- Severe prematurity.
- The gap between proximal and distal pouch is more than 2.5 cm.

Treatment of cardiac anomaly takes precedence over correction of esophageal atresia. Primary repair can be done after treatment of pneumonia or sepsis.

Staged Operation

The indications for staged operation are:

- If primary repair cannot be done due to reasons mentioned in delayed surgical repair.
- Failed primary repair.
- Long gap between two esophageal pouchs, viz. in type I esophageal atresia, where gap is usually more than 3 to 4 cm.

Stages of surgical correction are:

- Left cervical esophagostomy and feeding gastrostomy immediately after birth.
- Thoracotomy and ligation of tracheoesophageal fistula after 2 to 3 weeks of stage I.
- Replacement of the gap between proximal and distal esophagus by isolated vascularized segment of colon or by gastric tube is done at 6 to 8 months of age.

Postoperatively baby is managed as per the standard guidelines. Feeds through transanastomotic tube maybe started after 48 to 72 hours following X-ray chest. Barium study is done 8 to 10th postoperative day (Fig. 3). If there is no leak, tube is removed and baby is given oral feeds. Postoperative esophageal dilatations are started three weeks after primary repair, if necessary.

Complications

Early

- Pneumothorax
- Anastomotic leak—Diagnosed by appearance of saliva in the chest drainage tube and collection of fluid in X-ray chest.

Fig. 3: Contrast study done on 8th postoperative day following primary repair of esophagus

- Recurrence of fistula.
- Pulmonary atelectasis or infection.

Late

- Anastomotic stricture.
- Gastroesophageal reflux (GER).
- GER occurs in about 50 to 55 percent cases initially it is managed conservatively. However in about 5 to 8 percent cases fundoplication maybe necessary.
- Tracheomalacia.

Tracheomalacia is a structural and functional weakness of trachea, resulting in partial respiratory obstruction in approximately 10 to 12 percent cases. Presenting features are:

- Difficulty in feeding due to respiratory problems.
- Cyanotic attacks and/or apneic episodes.
- Peculiar barking cough.

Treatment is conservative, only in some selected cases aortopexy maybe necessary.

CONGENITAL DIAPHRAGMATIC HERNIA

Congenital diaphragmatic hernia (CDH) is defined as herniation of the intestine into chest through a congenital defect in the diaphragm. Diaphragmatic hernia are of two types:

- *Bochdalek hernia:* Herniation of the bowel in the chest is through the posterolateral defect in the diaphragm. This is the most common type of CDH.

- *Morgagni's hernia*: Herniation is through the anterior defect in the diaphragm.

Incidence of CDH varies from 1 in 2200 to 1 in 5000 livebirths. The incidence is much higher in stillborn. 85 percent Bochdalek type CDH occurs on left side. Less than 1 percent are bilateral. Female baby is affected twice as common as male. Cardiac and neural tube defects are most common associated anomalies.

Pathophysiology

Developing fetal lung is compressed by herniated abdominal viscera in the chest, which leads to pulmonary maldevelopment and lung hypoplasia resulting in:

- Reduction in alveolar surface for gaseous exchange.
- Decreased and abnormal pulmonary vasculature. There is muscular hyperplasia in small pulmonary arteries.
- Exaggerated abnormal response of abnormal pulmonary vasculature to hypoxia, hypercarbia and acidosis resulting in right to left shunting through ductus arteriosus and foramen ovale.

The net outcome of the lung hypoplasia and abnormal pulmonary vasculature in CDH is:

- Hypoxia and hypercarbia.
- Metabolic acidosis.
- Persistent fetal circulation (PFC).

Antenatal Diagnosis

Antenatal diagnosis of CDH is possible as early as 15th week of gestation on routine antenatal maternal sonography. The readily detectable features are:

- Presence of abdominal viscera in the chest.
- Polyhydramnios.

Fig. 4: Plain X-ray chest and abdomen with nasogastric tube in stomach: Left sided congenital diaphragmatic hernia

- Mediastinal displacement.
- Absence of intra-abdominal stomach bubble.

Presenting Features

Presenting features are marked respiratory distress, which include:

- Tachypnea, dyspnea, sternal recession, expiratory grunt and cyanosis.
- Scaphoid abdomen.
- Breath sounds are absent or diminished on affected side of the chest.
- Apex beat is shifted to the right side in the commonly present left sided CDH.

Investigations

- X-ray chest combined with abdomen in erect posture is usually the only investigation required to confirm the diagnosis. It will demonstrate presence of stomach and intestines in the chest and the mediastinal shift, along with paucity or absence of gas shadows in the abdomen. Diaphragmatic margin is absent (Figs 4 and 5).
- Contrast study is usually not done. It maybe done when right-sided CDH is suspected.
- Ultrasonography identifies and measures the diaphragmatic defect.

Differential Diagnosis

Differential diagnosis of CDH include the following:

- Congenital cystic adenomatoid malformation of the lungs.
- Pulmonary cystic lesions.

Fig. 5: Right sided CDH

- Staphylococcal pneumonia with cysts.
- Pneumothorax.

To differentiate above conditions from CDH an X-ray chest and abdomen erect posture with nasogastric tube placed in the stomach is taken. In CDH, the nasogastric tube lies in the chest, while in other conditions it lies in the abdomen.

Management

Current trends of management are delayed surgical approach, instead of an early and immediate surgical intervention, which was earlier considered as important factor in survival.

Preoperative Management

- As soon as the baby with CDH is admitted, size 6 or 8 F sterile nasogastric tube is passed to decompress the stomach to facilitate respiration.
- Routine neonatal care including intravenous fluids, antibiotics, temperature maintenance, monitoring of vital signs and management of hypoglycemia, metabolic acidosis are continued.
- To maintain adequate tissue perfusion without causing pulmonary overload, large volumes of crystalloid maybe necessary.
- Oxygen should not be given by nasal catheter or by face mask, as significant amount of oxygen will enter stomach causing its distension, which will further compromise respiration. Oxygen should be given through oxygen hood.
- If there is respiratory distress and hypoxia, endotracheal intubation must be done and ventilatory support must be started immediately.
- Ventilatory requirements in CDH:
 - Hypoplastic lungs require higher pressure for inflation, but higher pressures can rupture the alveoli causing pneumothorax. Therefore, if with ventilatory support, there is sudden deterioration in oxygen saturation levels, pneumothorax must be suspected and immediate intercostal chest drain under water seal must be put in. The pneumothorax can occur on either side of the chest.
 - To maintain relatively low ventilatory pressure to avoid pneumothorax, following are necessary:
 - i. High oxygen concentration.
 - ii. Rapid respiratory rate.
 - iii. Low tidal volumes.
 - Though conventional mechanical ventilation is usually started. However if it is ineffective, High Frequency Ventilation (HFV) may be given.
 - Objectives of the ventilatory support are to maintain postductal:
 - i. pO_2 above 40 to 50 mm Hg
 - ii. pCO_2 less than 30 mm Hg
 - iii. pH above 7.5

The aim of the preoperative management is to prevent hypoxia, thus preventing persistent fetal circulation (PFC) and persistent pulmonary hypertension (PPH).

Operation

Congenital diaphragmatic hernia (CDH) is not considered as a dire emergency where immediate operation is required. Current trend is preoperative resuscitation, with basic aim to correct hypoxia, hypoperfusion, and metabolic acidosis. This is associated with much improved survival.

After resuscitation, baby is operated. Repair of the diaphragmatic hernia is done through abdominal approach.

Postoperative Management

Ventilatory support is continued, by using low tidal volume, low inspiratory pressure and high respiratory rate. Aim is to minimize barotraumas, while maintaining normal pH and pCO_2 . Hyperventilation has been recommended, but permissive hypercapnea is gaining wider popularity. Usually the infant is weaned off the ventilator between 48 and 72 hours.

Complications

- During surgery abdominal viscera maybe injured or adrenal gland maybe included in the suture while closing the defect of the diaphragm.
- Damage to ipsilateral hypoplastic lung by overenthusiastic resuscitation resulting in overinflation, rupture and pneumothorax. This can happen even on contralateral side.
- Persistent respiratory insufficiency due to PPH or PFC.

Future Management Strategies

Fetal Surgery

In some centers in USA this is being done successfully. Repair of the diaphragmatic defect is done in the fetus and pregnancy is allowed to continue.

PLUG (Plug the Lung until it Grows)

Trachea of the fetus is plugged. Accumulation of secretions in the lungs pushes the herniated abdominal contents back into abdomen. Lungs grow normally. This procedure is still in the experimental stage.

CONGENITAL LOBAR EMPHYSEMA

Hyperinflation of a lobe or a segment of the lung resulting in compression or atelectasis of the adjacent normal lung and displacement of mediastinum characterizes congenital lobar emphysema (CLE). Sometimes, the hyperinflated lung may herniate across the midline. Hyperinflated lung does not participate in the normal gaseous exchange in the lungs, resulting in respiratory insufficiency.

The approximate incidence reported in various reports is 1 in 5000 to 7000 live born babies.

Left upper lobe is most commonly affected (45%) followed by right middle lobe (30%), right upper lobe (21%) and both lower lobes in about 1 to 2 percent cases.

Etiopathogenesis

Bronchial cartilage of the affected lobe is abnormal, causing partial airway obstruction. The bronchial cartilage maybe either absent, hypoplastic or dysplastic.

Macroscopically affected lobe is markedly distended and fails to collapse. On microscopic examination there is overdistention of alveoli and alveolar ducts. There is variable degree of fragmentation and rupture of alveolar walls.

Pathophysiology

Due to abnormal bronchial cartilage, the bronchi remains collapsed during passive process of expiration and the air, which entered the lobe during the active process of inspiration, remains trapped inside. With each breath the affected lobe distends with trapped air. Overdistention of the lung results in respiratory distress which gradually increases in intensity.

Presenting Features

The baby appears normal at birth. The characteristic features of congenital lobar emphysema usually occur at about 3 to 4 weeks of age after birth. The symptoms are relentlessly progressive after onset.

Investigations

- *X-ray chest:* Plain X-ray chest confirms the diagnosis in large majority of the cases. It reveals:
 - Overdistention of one lobe with reduced vascular and bronchial markings.
 - Mediastinal shift and herniation of emphysematous lung on other side.
 - Atelectasis of the adjacent lobe.
- CT scan: Confirms the findings of X-ray chest.

Treatment

Conservative management is contraindicated. Surgical treatment is lobectomy of the affected lobe.

PNEUMOTHORAX

Accumulation of the air in pleural space is defined as pneumothorax. Pneumothorax under pressure when there is one-way valve effect, i.e. air can enter pleural space but cannot escape out is defined as tension pneumothorax. It is a rapidly fatal condition in the neonates.

Overall incidence is 0.5 to 2 percent in all neonates. The incidence is higher in low birth weight babies. Incidence of pneumothorax is as high as 38 percent in babies

of hyaline membrane disease who are on mechanical ventilation.

Symptoms

Severity of symptoms is directly proportional to tension within mediastinum or in pleural cavity. The common presenting features are:

- Sudden onset of respiratory distress. Tachypnea, dyspnea, tachycardia, retraction of chest wall and cyanosis occurs rapidly.
- Respiratory distress is followed in rapid succession by apnea, bradycardia and cardiac arrest.

Diagnosis

Chest X-ray in upright position confirms the diagnosis. In newborn, narrow beam of fiberoptic light can indicate presence of pneumothorax (Fig. 6A and B).

Fig. 6A: Pneumothorax demonstrated by fiberoptic light. The other baby is with normal chest for comparison (*For color version see plate 1*)

Fig. 6B: Plain X-ray of chest: Pneumothorax

Treatment

- Intercostal chest tube in pleural cavity with under water seal drainage must be done immediately. The intercostal chest tube is inserted in 3rd or 4th intercostal space in anterior axillary line to avoid injury to enlarged thymus in neonates.
- In tension pneumothorax, if the baby is in impending danger of cardiac arrest, a needle maybe inserted in the chest to convert tension pneumothorax into open pneumothorax to be followed by intercostal chest tube insertion.

GASTROINTESTINAL TRACT LESIONS

Emergencies caused by GIT lesions may present with following signs and symptoms:

Abdominal Distention

- Intestinal obstruction
- Pneumoperitoneum
 - Perforation of bowel
Perforation of bowel: Perforated stomach is associated with large amount of intra-abdominal air. At times it is necessary to aspirate air from abdomen to relieve respiratory distress prior to definitive surgery.
 - Pulmonary air leak
Pulmonary air leak due to increased intrapleural pressure at the time of first breath after the birth of baby results in pneumothorax. The leaked air may dissect into peritoneal cavity, especially in the babies who are on mechanical ventilation.

Vomiting

- Bilious vomiting
Intestinal obstruction. The dictum is, if the baby has bilious vomiting, it is considered as intestinal obstruction until proved otherwise.
- Non-bilious vomiting
Some of the important causes of non-bilious vomiting are:
 - Gastroesophageal reflux.
 - Sepsis with ileus.
 - Decreased bowel motility: Prematurity, antenatal maternal sedation, hypothyroidism.
 - NS lesion: Intraventricular hemorrhage.
 - Lesions above ampulla of Vater.
 - Upper duodenal stenosis.
 - Annular pancreas (rare).

Failure to Pass Meconium

- Anorectal malformation.
- Hirschsprung's disease.

- Meconium plug syndrome.
- Meconium ileus.

Failure to Pass Stool after Initial Passage of Meconium

- Volvulus
- Malrotation
- *Ileal atresia:* Baby may pass small amount of grayish-green meconium once or twice after birth, but later there is absolute constipation.

Hematemesis or Blood in Stool

- Neonatal necrotizing enterocolitis.
- Stress ulcers in stomach.
- Coagulation disorders.

NEONATAL INTESTINAL OBSTRUCTION

Intestinal obstruction is one of the most common surgical emergencies in the neonates. Surgical causes of the intestinal obstruction in the neonates can be broadly divided according to site of obstruction as follows:

Duodenum

- Duodenal atresia or stenosis.
- Malrotation of the intestine.
- Annular pancreas.

Jejunum and Ileum

- Atresia or stenosis.
- Meconium ileus and peritonitis
- Neonatal necrotizing enterocolitis.

Colon

- Hirschsprung's disease.
- Meconium plug syndrome.

Presenting Features

Vomiting

Bilious vomiting is indicative of intestinal obstruction in the babies, until proven otherwise.

Failure to Pass Meconium

- Meconium is normally passed within 6 to 8 hours after birth. Delayed or failure to pass meconium within 24 hours or more after birth is suggestive of intestinal obstruction. In Hirschsprung's disease there is either delayed passage of meconium or it is passed after suppository or per rectal examination.
- In intestinal atresia, baby may pass meconium once or twice after birth, but it is small in amount and is pale or light green in color.

Fig. 7: Duodenal obstruction: Characteristic double bubble shadow in X-ray of abdomen

Fig. 8: Jejunal atresia: X-ray of abdomen shows triple bubble shadow

Abdominal Distention

Abdominal distention depends on the site of obstruction. It is minimal or absent in duodenal obstruction. Abdominal distention is maximum in low intestinal obstruction viz. ileal atresia or Hirschsprung's disease.

Investigations

X-ray Abdomen

Plain X-ray abdomen taken in upright position is very essential and gives vital clues for the diagnosis. In some cases it is diagnostic. Some of the observations are as follows:

- *Fluid levels:* Double bubble shadow is diagnostic of duodenal obstruction. Three bubbles are highly suggestive of jejunal atresia, while multiple fluid levels indicate ileal obstruction specially if there is one large fluid level along with multiple fluid levels (Figs 7 and 8).
- *Pattern of bowel loops:* For example, step ladder pattern in mechanical obstruction.
- *Presence of free air:* Indicate bowel perforation.
- *Intramural gas indicates:* Neonatal necrotizing enterocolitis.

Contrast Enema

It is done when clinical features are suggestive of Hirschsprung's disease.

Ultrasonography

Ultrasonography of the abdomen is useful if there is any mass lesion or free fluid in the abdomen.

Complications

Failure to recognize early signs and symptoms and delay in the management leads to following complications, which significantly increases the morbidity and mortality.

- Respiratory distress due to progressive abdominal distention.
- Dehydration and electrolyte imbalance.
- Aspiration pneumonia.
- Apnea.
- Hypoglycemia.
- Metabolic acidosis.
- Hypothermia.
- Shock.

Peripheral circulatory failure indicates bowel perforation with peritonitis, gangrene of intestine, septicemia or prolonged hypovolemia due to inadequate fluid resuscitation.

Management

- First step is to stop oral intake.
- *Nasogastric aspiration:* 8 or 10 F sterile nasogastric tube is placed in position in the stomach and aspiration of accumulated gastric fluid is done regularly.
- *Intravenous fluids:* IV access must be established immediately. Maintenance and correctional IV fluid is started.
- *Electrolyte imbalance:* Serum electrolytes are monitored regularly and electrolyte imbalance is corrected accordingly.
- *Blood volume:* Restoration of blood volume is mandatory. Hematocrit is monitored frequently. Intravenous fluid, plasma or blood may be transfused depending on the requirement.
- *Metabolic acidosis:* Blood gas analysis is done and metabolic acidosis is corrected.
- *Antibiotics:* Broad spectrum prophylactic antibiotics are started and are given intravenously.
- *Adequate ventilation:* If necessary supplemental oxygen or assisted ventilation may be given.

Baby with intestinal obstruction should not be operated until fluid deficit, electrolyte imbalance and metabolic disorders have been corrected and blood volume is fully restored. After complete resuscitation, exploratory laparotomy should be done and causative lesion is corrected. Survival largely depends on adequate and effective pre and postoperative care.

ANORECTAL MALFORMATIONS

Absence of anus in the perineum is traditionally known as imperforate anus (Fig. 9). Now this anomaly is termed as anorectal malformation (ARM), as in a significant percentage of cases, distal rectal end communicates either with urinary tract in the male babies, genital tract in the female babies or opens on the perineal surface with a fistulous tract in either of them. The reported incidence of ARM is 1 in every 2,000 to 4,000 live births.

Fig. 9: Imperforate anus (For color version see plate 2)

Antenatal sonographic findings indicative of ARM are:

- Dilated bowel loops.
- Intraluminal calcification of meconium, when a rectourinary fistula is present.
- Absence of anal ultrasonographic characteristics in the perineum, at 25 to 30 weeks of gestation.

ARM is classified as supralelevator (high) or translevator (low) anomaly depending on whether rectum terminates above or below the levator ani muscle complex. Supralelevator anomaly may communicate with urethra in male and genital tract in female baby.

Associated Anomalies

Genitourinary Anomalies

Incidence of associated genitourinary (GU) anomalies varies from 25 to 60 percent.

The incidence is more in high ARM.

Sacrum

Sacral deformities are frequently associated with ARM. The various associated sacral anomalies are:

- Hemisacrum.
- Absent sacral vertebrae: If more than two sacral vertebrae are missing, it may be associated with incontinence.

Anomalies of Vertebral Column

- Hemivertebra
- “Tethered” cord

Other Associated Anomalies

Cardiac, musculoskeletal and esophageal atresia are other associated anomalies.

Management

The first step in the management is to confirm the diagnosis and to decide whether protective colostomy is required or not.

Management in the Male Baby

Postnatal history and clinical examination provide important clues to the diagnosis:

History: In the male baby, history of the passage of meconium in the urine along with absence of normal opening in the perineum, indicates ARM with rectourethral fistula. No further investigations are required. As an initial management protective colostomy is done.

Clinical Examination

- Presence of anocutaneous fistula, anterior anus or any fistulous opening in the perineum with passage of meconium confirms low anomaly. Anoplasty is done.

Fig. 10: Invertogram: Supralelevator anomaly

Fig. 11: Invertogram: Translevator anomaly

- If there is no information on clinical examination or urine analysis, then investigations are done to confirm the diagnosis.

Investigations

- Rice invertogram or cross table lateral X-ray, which determines the level of termination of blind rectal pouch. Following are prerequisites of invertogram:
 - Invertogram should be done at least 12 to 14 hours after birth.
 - Baby should be kept hanging upside down for at least 2 to 3 minutes.
 - Hips are kept straight so that both the femurs do not obstruct the pubic bone.
 - The true lateral view is taken.
 - X-ray beam is focused at greater trochanter.
- After obtaining invertogram or cross table lateral X-ray following landmarks are identified:
 - *P-C Line*: A line is drawn from center of pubic bone to last piece of sacrum.
 - *I Point*: The lower most comma shaped tip of ischial bone is marked as “I” point.
- Following are evaluated on invertogram:
 - Level of gas in the blind rectal pouch (Figs 10 and 11):
 - i. If above P-C Line: It indicates low anomaly
 - ii. If below P-C line: It indicates high anomaly
 - *Sacral anomaly*: Sacrum is evaluated for any anomaly. If less than two segments of sacrum are present, it is strongly suggestive of fecal incontinence.
 - *Bowel loop pattern*: There may be a very large air fluid level in the pelvis suggestive of short colon syndrome (Fig. 12)

Fig. 12: X-ray of abdomen demonstrating very large air fluid level characteristic of pouch colon syndrome

- *Associated anomaly*: Identify any associated vertebral, cardiac, or chest anomaly.
- Ultrasonography, CT scan or MR imaging: Either of these investigations may be done to determine the distance between rectal pouch and perineal skin. After confirming the level of rectal pouch following is the surgical management in the male baby:

- *Low anomaly*: When bowel to perineal skin distance is less than 1 cm or distal bowel gas shadow is above P-C line in invertogram, then anoplasty is done.
- *High anomaly*: When bowel to perineal skin distance is more than 1 cm or gas shadow is below P-C line, protective colostomy is the first step. Later investigations are done and PSARP is planned.

Management in the Female Baby

Clinical examination determines the type of anorectal anomaly. Usually investigations are not necessary to confirm the diagnosis.

Three Openings in the Perineum

If clinical examination reveals three openings in the perineum, it indicates low anomaly. The surgical options are:

- Ano-cutaneous fistula or anterior perineal anus: Anoplasty is done.
- Vestibular anus: Either of the following procedure may be done:
 - Anal transposition, or
 - Protective colostomy followed by mPSARP.

Two Openings in the Perineum

Openings seen are of urethra and vagina. It is an uncommon anomaly. In these cases, protective colostomy is done followed by PSARP.

One Opening in the Perineum

One opening in the perineum confirms the diagnosis of cloacal malformation. A protective colostomy, usually in the proximal transverse colon is done. Later the baby is fully investigated. Surgical procedure depends on the exact malformation, which differs from one patient to another.

COLOSTOMY

Protective colostomy is done as divided colostomy in the distal part of the descending colon or in proximal part of the sigmoid colon.

Investigations to be done after Colostomy

- To evaluate length of distal bowel and identify the presence of fistula with urinary tract:
 - Distal cologram:
 - Cystourethrogram:
- To evaluate associated urinary tract anomalies:
 - Intravenous urogram or contrast enhanced CT scan to identify renal anomalies
 - MCU to confirm the presence or absence of megaureter, vesicoureteric reflux, or any other bladder or ureteric anomaly.

- Renal scan (DTPA or MAG3) maybe done to quantify renal functions and anomalies.
- To evaluate other associated malformations. If clinical symptoms or examination suggests cardiac or anomaly of any other organ, then appropriate investigations are done.

Posterior Sagittal Anorectoplasty

After complete investigations posterior sagittal anorectoplasty is done at 4 to 6 months of age as a definitive procedure.

HIRSCHSPRUNG'S DISEASE

Hirschsprung's disease is the congenital absence of the ganglion cells both in the muscle layers (Auerbach's plexus) and in the submucosa (Meissner's plexus), with presence of hypertrophic nerve trunks in the distal bowel, beginning with aganglionic segment and including the internal sphincter. The aganglionic segment extends proximally to varying distances. This anomaly results in functional obstruction with dilatation and hypertrophy of the proximal ganglionic segment.

The incidence of Hirschsprung's disease ranges from 1 in 4000 to 1 in 7000 live births. Male to female ratio is 4:1 but, long segment aganglionosis is more common in female babies.

Pathology

The characteristic feature of Hirschsprung's disease is absence of ganglion cells in both submucosal (Meissner's plexus) and Intermuscular (Auerbach's plexus) layers, associated with marked increase in nerve fibers extending into submucosa. The process of aganglionosis is always continuous and uninterrupted. There are no skip lesions.

Proximal to aganglionic segment, there is transitional zone, in which ganglion cells are few in number, hypertrophied nerve fibers are present and colonic motility is abnormal.

In the normal ganglionic intestine a balance exists between contractile and relaxation activity, which keeps smooth muscle finely controlled. In aganglionic segment this fine balance is disturbed, which results in increased smooth muscle tone.

Presenting features in the neonates are:

- Delay of more than 24 hours in passage of first meconium after birth.
- As acute intestinal obstruction: There is history of delayed passage of meconium after birth or baby did not pass meconium after birth, followed by abdominal distension and bilious vomiting. Per rectal examination reveals empty rectum, but withdrawal of finger results in passage of meconium and gas. Abdomen becomes soft and vomiting stops. The cycle repeats again after some interval.

Fig. 13: Hirschsprung's disease: X-ray of abdomen demonstrating distended proximal colonic loops

Fig. 14: Hirschsprung's disease: Barium enema

Investigations

Plain X-ray abdomen in erect posture:

- In the neonates: It is difficult to differentiate between small and large bowel in the neonates.
 - X-ray could be normal if bowel is deflated specially after passing stool or after per rectal examination.
 - Dilated proximal colon may be seen (Fig. 13).
 - Multiple fluid levels: Indicates intestinal obstruction. It could be because of Hirschsprung's disease.

Contrast enema

- It is done in an unprepared colon.
- Barium diluted with normal saline is used.
- Oblique views are taken to visualize whole length of the colon.
- 24 hours postevacuation films must be taken.
- The findings are:
 - Normal caliber distal colon with hugely dilated proximal colon (Fig. 14).
 - Presence of retained barium in 24 hours post evacuation film is very strongly suggestive of Hirschsprung's disease.

Management in the neonates is as follows:

Uncomplicated

After resuscitation and investigations to confirm the diagnosis, colostomy is done. Site of colostomy depends on the extent of aganglionosis.

- Transverse colostomy is done, if aganglionosis extend up to rectosigmoid junction.

- Terminal colostomy is planned in long segment cases. The colostomy is done in the ganglionic colon, just proximal to transitional zone.

Complicated

- There is acute intestinal obstruction or bowel perforation. The management is rapid resuscitation and emergency laparotomy and colostomy.
- *In enterocolitis:* Management is very aggressive and includes intravenous fluids, blood or fresh frozen plasma. Broad-spectrum antibiotics, warm saline irrigation of colon and rectum.

After stabilization of clinical condition, colostomy is done in the ganglionic segment. Definitive surgery is done at the age of 4 to 6 months. There are various techniques for definitive pull through. The basic aim of all the surgical procedures is:

- Excision of aganglionic segment.
- Posterior internal sphincterectomy.
- Anastomose the ganglionic segment to anal canal.

There are various techniques both as single or multistage, through abdomino-perineal approach or as endorectal-procedure. The procedure can be done through laparoscopic assistance also.

LARGE SKIN DEFECTS

Omphalocele and Gastroschisis

Omphalocele and gastroschisis represent abdominal wall defects in the newborn. Combined incidence of both is approximately 1 in 2000 live births.

Congenital Hernia of the Cord

When diameter of the hernia of the umbilical cord is less than 4 cm and the umbilical ring defect is less than 2.5 cm. It is defined as congenital hernia of the cord. It contains only loops of intestine.

It is different from umbilical hernia, in which the protrusion is covered by skin. In congenital hernia of the cord protrusion, containing bowel loops, is covered by transparent membrane.

Primary surgical closure is the treatment of choice, which includes replacing the intestinal loops back into the peritoneal cavity, excision of the sac and primary closure of the peritoneum, muscles and the skin. The prognosis is excellent.

Omphalocele (Exomphalos)

Omphalocele is the herniation of the intra-abdominal contents through the umbilical ring. The herniated contents are covered by translucent, avascular membrane, which consists of amnion, Wharton's jelly, and yolk sac membrane from out to inside (Fig. 15).

The umbilical cord is inserted on top of the sac. The umbilical vessels radiate out on the wall of the sac. The size of the defect varies from 5 to 12 cm. The contents of the sac are usually loops of small and large intestine. In approx 12 to 28 percent liver is also in the sac. Rectus muscles are situated at the margin of the defect.

Antenatal Diagnosis

It is possible to diagnose omphalocele and gastroschisis antenatally by:

- Maternal ultrasonography.
- Maternal serum alpha-fetoproteins: It is raised in both conditions.

Amniocentesis and chromosomal analysis should be done in omphalocele to detect associated anomalies as early as 10th week of gestation.

By using transvaginal ultrasonography, omphalocele is detected by presence of membranous sac and liver protruding from abdomen. Gastroschisis is diagnosed by presence of free-floating loops of intestine in the amniotic fluid.

Associated congenital anomalies are present in 35 to 78 percent of babies with omphalocele.

Complications

- Rupture of the sac. Rupture of the sac maybe before birth, during labor or after birth (Fig. 16).
- Infection and sepsis.
- Hypothermia and hypovolemia may result from evaporative water losses.

Management

Preoperative Management

- Examination of the sac: Whether the sac is intact, or ruptured. Evaluate the size and contents of the sac.
- Nasogastric tube is passed and NG aspirations are done regularly to prevent vomiting and aspiration of gastric contents. It also decompresses the stomach thus facilitates respiration and prevents dilatation of the intestines.
- Intravenous fluids and antibiotics are started.
- Hematocrit, serum electrolytes, blood sugar and arterial blood gases are done.
- Chest and abdominal X-rays are done.

Non-operative Management

Indications of non-operative management are:

- Large omphalocele with intact sac and no associated anomalies.
- Large omphalocele, with intact sac but associated with severe life-threatening cardiac anomaly, the correction of which is more urgent.
- Associated anomalies, which interfere with primary repair of omphalocele.

Fig. 15: Omphalocele (For color version see plate 2)

Fig. 16: Omphalocele (Ruptured sac)
(For color version see plate 2)

0.25 percent solution of mercurochrome in alcohol or betadine lotion is applied over the sac 6 to 8 hourly till solid Escher forms. Epithelialization takes 10 to 12 weeks and results in ventral hernia, which can be repaired later at the age 2 to 3 years.

Operative Management

Operative management is either primary closure or staged repair.

Primary Repair

Small or medium sized omphalocele can easily be repaired by primary closure.

If the defect is large, or cardiac or respiratory monitoring suggests impending problems later, either a staged repair maybe done or silastic mesh maybe used in the repair.

Staged Repair

Indications are:

- Primary closure is not possible due to above mentioned complications.
- Large omphalocele with ruptured sac.
- Large omphalocele containing liver.
- The various procedures for staged repair are as follows:
 - Skin flap closure over intact sac.
 - Skin flap closure.
 - Prosthetic “Silo” closure.

GASTROSCHISIS

There is a full thickness defect in the anterior abdominal wall, which is approx. 2 to 5 cm on the right side of the umbilical cord.

Gastroschisis has following characteristic features. There is no sac, nor there is any remnant of the sac.

- Defect in the anterior abdominal wall is about 2 to 5 cms, on the right side of normally situated umbilical cord. The defect is separated from the cord by a bridge of skin.
- Bowel loops are eviscerated, which are dilated, walls are thickened and edematous. Bowel loops are covered by fibrinous adhesions. Stomach or colon maybe eviscerated, but liver never herniates (Fig. 17).
- Abdominal cavity is small and appears empty.
- Associated major malformations are infrequent.
- Prematurity is very common (60–65%).

Gastroschisis is a rare condition. Exact incidence is not known.

Associated Anomalies

- Non-rotation or malrotation of the gut is frequently associated.

Fig. 17: Gastroschisis (For color version see plate 2)

- Ischemia or gangrene of the parts of the intestine, because of small defect in the abdominal cavity due to which blood supply maybe compromised.
- Cryptorchidism (18-47%).

Antenatal Diagnosis

Gastroschisis can be easily diagnosed antenatally by ultrasonography due to following characteristic features:

- Normally placed umbilical cord.
- Absence of sac or covering membrane
- Free floating eviscerated intestinal loops, through abdominal wall defect.
- Thickening of bowel loops.
- Absence of major associated anomalies.

Management

Preoperative Management

- Due to eviscerated bowel loops there is excessive evaporative losses resulting in hypovolemia and hypothermia. Therefore:
 - Eviscerated bowel loops are covered with warm moist saline packs and wrapped in a polythene sheath so as to prevent evaporation or maybe simply placed in polythene bag.
 - Intravenous fluids are given in the dose of 150 to 200 ml/kg/day so as to compensate losses from the exposed bowel loops in the initial phase.
 - Body temperature is maintained.

- Nasogastric tube is passed and aspirations are done to decompress stomach.
- Warm saline rectal washes are given to evacuate meconium.

Operative Management

Primary Closure

Primary closure is possible in large majority of the cases. It is done in the same way as omphalocele.

Primary repair should be done as early as possible after birth, if possible even immediately after birth.

With modern techniques of neonatal intensive care and aggressive pre and postoperative management the babies with gastroschisis and omphalocele have an excellent survival rate.

EXSTROPHY OF THE BLADDER

Exstrophy bladder is an uncommon congenital malformation. The reported incidence is 1 per 30,000 to 50,000 live births. Male children are affected 2 to 5 times more than the female.

Presenting Features

The classic bladder exstrophy in male children is represented by:

- Absence of the anterior abdominal wall in the suprapubic area.
- Low placed or absent umbilicus.
- Absence of the anterior wall of the urinary bladder.
- Posterior wall of the bladder everts out due to intra-abdominal pressure.
- Open urethral plate, i.e. dorsum of the penis is open with cleft of the glans (epispadias). Prepuce is present only on ventral surface.
- Wide separation of the pubic symphysis with separation of rectus abdominis muscles.
- Penis is short and wide, as both the corpora are attached to widely separated pubic rami. There is dorsal chordee.

In female children besides abdominal and bladder wall defects, there is bifid clitoris and separation of labia. The vagina is short and anteriorly displaced.

Following anomalies are commonly associated with exstrophy bladder:

- Musculoskeletal anomalies.
- Due to pubic symphysis diastasis, there is external rotation of the hip, which alters the gait of the child.
- Vertebral anomalies.
- Anterior displacement of the anus, there may be rectal prolapse also.

Antenatal diagnosis is possible. Exstrophy bladder is strongly suspected if after 14 weeks of gestation urinary bladder is not demonstrated.

Investigations

No investigations are required to diagnose the condition. However, ultrasonography, renal scintigraphy and intravenous urography evaluate upper urinary tract.

Management

There are two major options in the surgical treatment of exstrophy of bladder:

- Primary reconstruction
- Urinary diversion
 - Primary reconstruction is a staged procedure, which is as follows:
 - 1st Stage:* “Turn In” or bladder closure
Preferably it is done within 72 hours after birth, as newborn is still under the influence of maternal hormone relaxin. During this period pelvic ring can be closed effectively without osteotomies.
 - 2nd Stage:* Epispadias repair
It is performed between 12 to 18 months of age.
 - 3rd Stage:* Bladder neck reconstruction
It is done at 3 to 5 years of age. Antireflux procedure is done simultaneously at the time of bladder neck repair.
 - 4th Stage:* Augmentation cystoplasty
If required, it should be done at the age of 8 to 10 years. The main indication is, if the capacity of the bladder is small but bladder neck functions are adequate.

Complications

- Wound dehiscence
- Urethral stricture
- Recurrent UTI
- Stitch abscess
- Urinary incontinence
 - Diversion of urine: It is not done in the neonates. Indications for urinary diversion:
 - Very small bladder with hypertrophied mucosa at birth.
 - Inadequate bladder capacity after bladder neck reconstruction.
- Failure to gain continence after primary reconstruction. There are following options for urinary diversion:
 - Colonic or ileal conduit.
 - Ureterosigmoidostomy: It is not a procedure of choice due to late complications.

SPINA BIFIDA

Spina bifida is defined as failure of the fusion of vertebral arches with or without protrusion of the meninges and dysplasia of the cord.

Spina bifida can be classified as spina bifida occulta and spina bifida cystica, which is associated with protrusion of the meninges with or without dysplasia of the cord.

The emergency situation is in following cases of spina bifida cystica:

- Meningocele with very thin sac about to rupture or ruptured sac. Rupture is within 4 to 6 hours after birth.
- Meningomyelocele: If there is CSF leak or neural plaque is exposed on the surface of the sac.
- Myelocele with leaking CSF presented within 4 to 6 hours after birth.

However, the surgical interference is deferred in following situations where spina bifida is associated with:

- Gross paraplegia
- Incontinence of urine and feces
- Large hydrocephalus
- Severe kyphosis or scoliosis
- Associated with complex congenital malformations, incompatible with life.

RETENTION OF URINE

Posterior Urethral Valves

Mucosal or membranous folds present in the posterior urethra, which act as one way valve, i.e. obstruct the flow of urine in antegrade direction, while allowing retrograde flow are termed as posterior urethral valves. These folds are not present in the normal urethra.

The classification by Young et al who described three types of valves is still valid. The three types are:

Type I

Ninety five percent of all PUV are Type I. There is a ridge on the floor of urethra continuous with verumontanum anteriorly. It divides into two processes, which are directed upward and forward and is attached to urethra in its entire circumference.

Valves are membranous, which maybe thin or thick and rigid. Degree of obstruction caused by the valves varies considerably.

Type II

This originates at verumontanum and passes along the posterior urethral wall towards bladder neck. These valves do not cause obstruction.

Type III

It is actually a membrane, lying transversely across the urethra. A small perforation is present in the center. It causes obstruction in both antegrade and retrograde direction. These valves are rarely present (2–3%).

Entire urinary tract proximal to PUV is affected in varying degrees depending on the severity of urethral obstruction. Urinary obstruction starts antenatally early in

the second trimester after normal differentiation of the urinary tract is complete and continues till birth and later.

Because of the obstruction in the posterior urethra there are secondary changes, which are as follows:

Prostatic urethra

Important changes are:

- Dilatation and elongation of posterior urethra
- Verumontanum is distorted.
- Ejaculatory duct maybe dilated with reflux of urine into vas deferens.

Bladder neck

- Bladder neck is hypertrophied and displaced anteriorly, but is often open.
- Usually bladder neck changes resolve once the valves are ablated and obstruction is relieved.

Urinary bladder

Secondary changes on the urinary bladder due to PUV are:

- There is hypertrophy and hyperplasia of the detrusor muscle.
- High intraluminal pressure.
- Increased residual urine.
- High pressure voiding.

Ureters

Raised intravesical pressure as a result of PUV, results in vesicoureteric reflux (VUR).

Kidney

- Hydronephrosis
Hydronephrosis is due to:
 - VUR
 - Obstruction: High pressures within bladder are transmitted to ureters and kidneys directly through hydrostatic pressure.
 - Due to abnormal ureteral bud which results in dysplastic kidney and dilated collecting system.
- Renal damage:
Renal damage is due to two components:
 - Renal dysplasia.
 - Obstructive uropathy.

Presenting Features

Posterior urethral valve presents with wide variety of symptoms, ranging from minor voiding disorders to complete retention of urine with metabolic problems and/or renal failure.

Presenting features in neonates vary according to severity of PUV. Neonate may present with:

- Severe respiratory distress due to pulmonary hypoplasia secondary to oligohydramnios due to decreased fetal urine production. Large majority of neonates with pulmonary hypoplasia and PUV die soon after birth.

- Intrauterine growth retardation, refusal to accept feeds, and vomiting. These symptoms indicate systemic illness due to nephropathy.
- Retention of urine, weak stream or dribbling of urine.
- Fever and sepsis due to UTI.

On examination, there is palpable mass in the abdomen, which may be distended bladder or hydronephrotic kidney.

Investigations

Antenatal

Antenatally PUV are diagnosed during routine maternal ultrasonography.

The critical time of detection of PUV is 24 weeks after gestation. U/S evaluation done before 24 weeks may not detect PUV. The ultrasonographic findings are:

- Bilateral hydroureteronephrosis.
- Dilated bladder with thick walls.
- Dilated posterior urethra and hypertrophied ladder neck.
- Increased renal echogenicity at mean age of 28 weeks of gestation is suggestive of obstructive uropathy. Echogenicity is normal in nonobstructive dilatation.

Postnatal

Ultrasonography: Routine abdominal ultrasonography confirms the findings of antenatal ultrasonography and if done through perineal approach, provide better confirmatory findings:

Voiding cystourethrogram (VCUG): It is the most reliable diagnostic investigation.

Renal Scintigraphy

DTPA or MAG -3 renal scan is done to assess differential renal functions.

Laboratory Evaluation

To evaluate renal functions and electrolyte status.

- Blood urea and serum creatinine levels are elevated.
- Metabolic acidosis.
- Hyperkalemia: If present it indicates a real threat.
- Urine examination: Routine and cultures to detect infection.

Management

The first priority is to relieve the urinary obstruction. A urethral catheter is passed under strict aseptic conditions. Urine is sent for routine examination and for cultures.

In severe case of PUV with pulmonary hypoplasia catheter drainage is the only management till pulmonary status improves.

In majority of the neonates, PUV are associated with following clinical problems:

- Uremia
- Dehydration and electrolyte imbalance
- Metabolic acidosis
- Infection
- Nutritional problems

Baby is resuscitated by intravenous fluids, electrolyte and acid base correction with broad-spectrum antibiotics.

Following options are available for the treatment of posterior urethral valves.

Ablation of Valves

Due to availability of modern pediatric instruments primary ablation of posterior urethral valve is routinely done as primary procedure. Valve ablation can be done by:

- *Cystoscope:* Pediatric cystoscope size 6 or 8 is passed per urethra. Bugbee electrode is used to fulgurate the valves. Valves are fulgurated at 11 and 4'o clock position.
- *Whitaker Hook:* It is a 6 Fr instrument, which has a crocheting hook on the end. It is passed in the urethra. It may be used either blindly or under fluoroscopic control to hook and disrupt the valves.
- *Nd-Yag Laser:* The Nd-Yag laser can fulgurate valves.

Urinary Diversion

The indications of urinary diversions are:

- Very sick baby
- Primary valve ablation is not possible either due to clinical condition of the baby or due to nonavailability of the proper instrument.
- There is gross bilateral vesicoureteric reflux.

Vesicostomy is the procedure of choice. Ninety percent patients improve and condition stabilizes even with VUR.

Long-term Results

Recent advances in the diagnosis and management have dramatically improved the survival. The mortality, which was approx. twenty five percent in 1960's is virtually nil now. However, patients with most severe form of disease are either still born or die soon after birth due to severe respiratory distress, as a result of associated pulmonary hypoplasia. These children do not present for the treatment of posterior urethra valves.

25 to 35 percent babies treated in the neonatal period develop end stage renal failure and may require renal transplantation. There is another group of babies, who do not develop end stage renal failure, but they also do not have enough renal functions to permit normal growth and development.

ACUTE SCROTUM

Torsion Testes

Seventy percent cases of torsion testes in neonates occur prenatally. Torsion is extravaginal, i.e. the twist occurs outside the attachment of tunica vaginalis.

The presenting features are:

- In prenatal torsion, the testes is nontender, firm, indurated, swollen with a slightly bluish cast.
- In postnatal torsion, testes is swollen and is extremely tender on palpation.
- Scrotal skin maybe erythematous or edematous.
- Transillumination is negative.
- Cremaster reflex is negative.

Diagnosis is made by clinical suspicion and physical examination. Ultrasonography employing Doppler flow studies can be useful.

Differential Diagnosis Includes

- Torsion of appendix of testes.
- Strangulated inguinal hernia.
- Scrotal hematoma following birth trauma secondary to breech delivery.

Epididymo-orchitis is never considered as a diagnosis in the neonates.

Treatment

Immediate surgical exploration of the affected scrotum should be done.

- If testes are necrotic: Excision of the gangrenous testes is done. Contralateral orchidopexy must be done.
- If torsion is recent:
 - Tunica vaginalis is opened.
 - Color of testes is noted.
 - Detorsion should be done.
 - If color improves, orchidopexy on both sides is done.

STRANGULATED INGUINAL HERNIA

Inguinal hernia is present in 5 percent premature babies weighing less than 1500 gm and in 30 percent weighing less than 1000 gm. It is more common in small for gestational age babies and in male. Incidence of strangulated hernia is very high in this group of babies.

Neonatal Blood Component Therapy

Anupam Sachdeva, Samridh Nagar, SP Yadav, Vasant Chinnabhandar

Rapid advances in medical care are continuously pushing the boundaries at which preterm neonates can be salvaged. With these increased rates of survival blood components tailored specifically to satisfy the needs of these very low birth weight (VLBW <1500 g) and extremely low birth weight (ELBW <1000 g) should be available.

WHY ARE THE GUIDELINES FOR NEONATAL TRANSFUSION NEEDED?

- Sick neonates are one of the most heavily transfused groups.¹
- Most neonatal transfusion practice remains opinion based and there is a diversity of opinion and practice.²⁻⁶
- The administration of blood products conveys a finite risk of transmitting potentially serious infections and is not without risk and cost.^{7,8}
- The most dynamic changes occur during the perinatal period and early infancy.

Blood Transfusion Practice Unique to the Newborn

- A child is not a miniature adult and a neonate is not a miniature child
- Neonatal physiology
- Neonatal immunology and compatibility testing
- Neonatal vascular access
- Small volume packs.

Unique Aspects of Neonatal Physiology

Infant Size and Blood Volume

Full-term newborns have a blood volume of approximately 85 ml/kg; preterm low-birth weight newborns have an average blood volume of 100 ml/kg. As survival rates continue to improve for infants weighing 1000 g or less at birth, blood banks will increasingly be asked to provide

blood components for patients whose total blood volume is less than 100 mL. The need for frequent laboratory tests has made replacement of iatrogenic blood loss the most common indication for transfusion of low-birth preterm neonates.⁹ However, the previous practice of replacing blood mL for mL is now giving way to replacement as needed to maintain a target hematocrit in certain clinical situations.

Newborns do not compensate for hypovolemia as well as adults. After ten percent volume depletion, a newborn diminishes the left ventricular stroke volume, without increasing the heart rate. To maintain systemic blood pressure, peripheral vascular resistance increases and this, combined with the diminished cardiac output, results in poor tissue perfusion, low tissue oxygenation, and metabolic acidosis.¹⁰

Erythropoietin Response

Erythropoietin response to hypoxia in newborns differs from that of adults and older children. In older children and adults, oxygen sensors in the kidney recognize diminished oxygen delivery and release EPO into the circulation. In the fetus, the oxygen sensor that stimulates EPO production is believed to be the liver, which appears to be programmed for the hypoxic intrauterine environment. This hypo-responsiveness to hypoxia protects the fetus from becoming polycythemic. Eventually, EPO production shifts from the liver to the kidneys, a developmental change thought to be regulated by time of conception, not birth, and possibly not beginning until term. After birth, it is the most immature infants who produce the least amount of EPO for any degree of anemia; this may reflect the absence of the developmental shift of erythropoietin production from the liver to the kidneys.¹¹ Circulating EPO levels are lower, for a given hematocrit, in preterm neonates.¹¹

Erythroid progenitor cells in the hypoproliferative bone marrow of these preterm infants show normal intrinsic sensitivity to EPO; clinical trials are in equivocal to evaluate treatment of the anemia of prematurity with recombinant human erythropoietin.¹² Sick preterm neonates who receive many transfusions shortly after birth have reduced circulating levels of fetal hemoglobin.

Cold Stress

Hypothermia in the newborn causes exaggerated effects, including increased metabolic rate, hypoglycemia, metabolic acidosis, and a tendency towards apneic episodes that may lead to hypoxia, hypotension, and cardiac arrest. Exchange transfusion with blood at room temperature may decrease a newborn's rectal temperature by 0.7 to 2.5°C, therefore, blood for exchange transfusion should be warmed. The usual method is to use an in-line warmer. Blood should not be warmed under a radiant heater (either large or small volumes), but small volumes of blood are sometimes placed in a temperature-controlled incubator, where there are safeguards against excessive warming. When transfusions are given to infants in the phototherapy unit, the tubing should be introduced through the side port, because red cells in tubing that enter the top port maybe hemolyzed.¹³

Immunologic Status

Infants have an immature humoral immune system, and any antibodies present derive almost entirely from the maternal circulation. Transplacental transfer of immunoglobulin and other proteins is independent of molecular size; IgG (150 kDa) is transferred much more readily than albumin (64 kDa). In humans, maternal IgM does not reach the fetus and IgA is not readily transferred, although low levels have been found in the newborn.

All four subclasses of IgG are transported across the placenta, but the rate varies between individual mother-fetus pairs. Early in pregnancy, IgG probably passes from mother to fetus by diffusion, and concentration in fetal serum is low for all subgroups. Between 20 and 33 weeks of gestation, fetal IgG levels rise markedly, apparently due to maturation of a selective transport system that involves, in part, specific protein receptors on the membrane of placental cells.¹⁰

IgG₁, the predominant subclass in maternal blood, crosses the placenta first and is transported in greatest quantity. Cord blood has higher antibody concentrations than maternal blood. Catabolism of IgG occurs more slowly in the fetus than in the mother, so that transplacental maternal antibody is conserved during the neonatal period. A fetus exposed to an infectious process *in utero* or an infant exposed shortly after birth may produce small amounts of IgM detectable by sensitive techniques, but unexpected red cell alloantibodies of either IgG or IgM class are rarely formed during the neonatal period.¹⁴

The cellular immune system of neonates is also immature. Graft versus host disease (GVHD) has been reported in newborns, most often in infants who had confirmed or suspected congenital immunodeficiency. It has, however, occurred in infants who received intrauterine transfusion followed by postnatal exchange transfusion.¹⁵

A proposed explanation is that lymphocytes given during intrauterine transfusion could induce host tolerance, impairing rejection of lymphocytes given in the subsequent exchange transfusions. GVHD is not considered a significant clinical problem in exchange transfusions in immunologically normal newborns, and irradiation of blood to prevent GVHD is probably unnecessary. However, some neonatal nursery units provide irradiated blood for low-birth weight, low-gestational age, or septic preterm neonates, based on the belief, not yet universally accepted, that such infants are immunologically more vulnerable to GVHD.¹⁵ Irradiation should be performed on blood for intrauterine transfusion and on all subsequent transfusions that this infant receives; directed-donor units should be irradiated.¹⁶

Metabolic Problems

Acidosis or hypocalcemia may occur after large volume transfusion because the immature liver of the newborn metabolizes citrate inefficiently. Immature kidneys have reduced glomerular filtration rate and concentrating ability, and newborns may have difficulty excreting excess potassium, acid, and/ or calcium.

Potassium

Although potassium levels increase rapidly in the plasma of stored red cells, small volume, simple transfusions have little effect on serum potassium concentration in newborns. It has been calculated that transfusion of 10 ml/kg of red cells (hematocrit 80%) obtained from a unit of blood stored for 42 days in extended storage medium, would deliver 0.1 mEq of potassium if transfused slowly to a 1 kg neonate.¹⁷

This is much less than the daily potassium requirement of 2 to 3 mEq/kg. Serum potassium may, however, rise rapidly after infusion of large volumes of red cells in such circumstances as surgery, exchange transfusion, or extracorporeal circulation, depending upon the plasma potassium levels in the blood and manipulation of the blood component.

In stored, irradiated blood, the problem of potassium leak is potentiated; it may be desirable, for selected patients, to wash irradiated cells if they have subsequently been stored.¹⁸ It is preferable to perform irradiation as close to the time of administration as possible.

2, 3-Diphosphoglycerate

Neonates with respiratory distress syndrome or septic shock have decreased levels of 2, 3-diphosphoglycerate

(2, 3-DPG). Alkalosis and hypothermia may further increase the oxygen affinity of hemoglobin, shifting the dissociation curve to the left and making oxygen even less available to the tissues. Arterial oxygenation may be further compromised by respiratory distress syndrome or other pulmonary disease. Mechanisms that compensate for hypoxia in adults, such as increased heart rate, are limited in newborns. If a large proportion of an infant's blood volume has come from transfusion, transfusion of 2, 3-DPG-depleted blood may cause problems that would not affect older children or adults. Since 2, 3-DPG levels decrease in stored blood, exchange transfusion in newborns should use the freshest blood conveniently available. For small-volume transfusions, the medical necessity for fresh blood has never been demonstrated and arguments have been raised to suggest it is unnecessary.

Why use Component Therapy and not Whole Blood?

- Whole blood consists of six important components, each with a specialized function
- Some components can only be given effectively as components
- Safe approach
- Reduces volume of transfusion
- Allows optimal usage of each donor unit of whole blood.

Problems Associated with Neonatal Transfusions

- Frequent multiple, small volume transfusions needed
- Concept of 'fresh blood'
- Widespread and unnecessary use of whole blood
- Blood component therapy not yet practiced
- Blood wastage
- Multiple donor exposure

Compatibility Testing in Neonates and Young Infants

Neonates and young infants are immunologically immature; hence alloimmunization to RBC antigens is rare during this period.¹⁹ AABB standards²⁰ require only limited pre-transfusion serologic testing for infants below 4 months of age. This must include ABO and Rh typing of red cells and a screen for red cell antibodies. Wherever possible, samples from both mother and infant should be obtained for initial ABO and RhD group determination. If an unexpected red cell antibody is detected in the infant's specimen or if the mother's serum contains a clinically significant red cell antibody, the infant should be given either red cell units tested and found to lack the corresponding antigen(s) or units compatible by antiglobulin cross-match; this should continue for as long as maternal antibody persists in the infant's blood.

It is unnecessary to test the infant's serum for anti-A and/ or anti-B unless there will be transfusion of non-group-O cells.

A positive DAT on the neonate's red cells or an atypical red cell antibody in maternal or neonatal serum suggests possible hemolytic disease of the newborn (HDN). In such cases, special serological procedures will be necessary to allow selection of appropriate blood group.

Concerns with Cytomegalovirus in Neonates

Cytomegalovirus may be transfusion-transmitted; however current transfusion practice has made this uncommon.²¹ There is a high-risk of CMV in fetuses and infants <1.5 kg.

The "Guidelines of the UK Transfusion Service" state that blood transfused in the first year of life should be CMV negative.²² However, in an emergency, transfusion of leucodepleted components is acceptable as other authorities recommend use of blood components leucodepleted to $<5 \times 10^6$ /unit.^{22, 23} These have a significantly reduced risk of CMV transmission.²³

Irradiation

Irradiation of blood components (especially all red cell and platelet components) to prevent GVHD is essential prior to transfusion in the following cases:

- Intrauterine transfusion (IUT)
- Exchange transfusion of red cells after IUT.
- Top-up transfusion after IUT.

For more details refer to Chapter 80 on "Transfusion of Blood Components in Children".

RBC TRANSFUSIONS

The most commonly needed blood component support for neonates is packed RBC (PRBC) transfusions. Availability of small volume aliquots should be ensured in neonatal care units to maximize utilization of blood products.

RBC Transfusions are Needed

- To ensure adequate oxygenation during intensive care periods.
- After intensive care, to treat clinically significant symptomatic anemia.

Are there any Methods to Assess Tissue Oxygenation?

- Peripheral fractional oxygen extraction (FOE)—This method deserves further assessment.²⁴
- Capillary whole blood lactate.²⁵⁻²⁸
- There is no practical method available to everyday neonatal practice that accurately assesses tissue oxygenation.

What are the factors that influence Tissue oxygenation?^{29, 30}

- Concentration and type of hemoglobin.
- The concentration of 2,3-DPG within the RBCs.
- Cardiopulmonary function of the neonate.

None of these variables apart from Hb are easily measurable in day-to-day practice.

Indications for PRBC in the Newborn

- *Antenatal:* Blood loss due to feto-maternal or feto-placental hemorrhage
- *Intrapartum:* Ruptured cord, placenta previa and abruptio placentae.
- *Postnatal:* GI hemorrhage, slipping of the cord ligature, internally following traumatic delivery, iatrogenic blood loss following blood sampling.

There are 3 major factors contributing to small volume RBC transfusion requirements in VLBW infants.

- The rapid decline in Hb levels that occurs in the first weeks of life to a nadir at 2 months of life.^{29,31} It must be remembered that concomitant with the decrease in absolute hemoglobin levels, the switch from HbF to HbA production is also occurring, so that the change in oxygen-carrying capacity is not so marked as the change in the total Hb level might suggest.
- The associated respiratory illnesses often present in these neonates first as RDS and then as BPD. There is necessity of maintaining hemoglobin values at a predetermined level in these neonates.^{32,33}
- Phlebotomy losses. Because of the need for laboratory monitoring of ill neonates and the relatively large volumes of blood required in relation to these tiny infants' total blood volumes, phlebotomy losses contribute significantly to the need for RBC transfusions in VLBW infants.³⁴ In sick, neonates red cell replacement is usually considered when approximately 10% of the blood volume has been removed.

Trends in Clinical Practice, Restrictive Policy and Some Practical Considerations

Decreased use of RBC transfusions, even in the most preterm newborns is not associated with an increase in complications. There is less evidence from the reverse situation that is, does maintaining a high Hb improve outcome in preterm neonates?

Hb limited oxygen unloading capacity to the tissues is rare even in intensive care. However, Brooks et al,³⁵ who looked at maintaining a packed cell volume >40 percent in preterm neonates in an attempt to reduce retinopathy of prematurity, also reported no reduction in important neonatal complications (IVH, CLD, NEC) as secondary outcome measures. This study only assessed preterm neonates greater than 28 days of age—that is, outside the intensive care period. However, the fact that a low hemoglobin or packed cell volume by itself (as opposed to clinical concern about the adequacy of tissue oxygenation) is the sole trigger factor for transfusion in many intensive care situations^{9,26} suggests that hemoglobin limited

oxygen unloading capacity to the tissues is rare, even during intensive care.

Dedicating aliquots form a single donation of red cells (or apheresis platelets) to allow sequential transfusions from the same donor for neonates who are likely to be repeatedly transfused is considered good practice. When red cells are transfused they are usually given in small volumes. A transfusion of 10 mL/kg of RBCs at a hematocrit >80% should raise the Hb by ~3 g/dL.

However, other recent research in preterm neonates suggests that large volume (20 ml/kg) RBC transfusions lead to larger rises in Hb and fewer overall transfusions than small volume transfusions (10 ml/kg).³⁶ This volume of packed RBCs is well tolerated in the vast majority of preterm neonates.³⁶

There are three clinical settings in which newborns may require large volume RBC transfusion (exchange transfusion, surgery with cardiopulmonary bypass or during treatment with extracorporeal membrane oxygenation (ECMO)).³⁷

RBC units for transfusion to neonates are often chosen from a fresh (<5 days old) RBC unit at the time of his/her first small-volume RBC transfusion.

In settings of large volume RBC transfusion, replacement of plasma coagulation factors is often also required so that WB or reconstituted WB, i.e. an RBC unit mixed with a unit of fresh frozen plasma (FFP), can be used. For WB, or the RBC unit for reconstituted WB, the choice of ABO group is the same as that described above for small volume RBC transfusions. The ABO group of the FFP must also be compatible with the baby's RBCs. This may mean that the ABO groups of the RBC unit and the FFP unit are different, e.g. for a group A baby with maternal anti-A in his plasma, a unit of reconstituted WB would be prepared using a group O RBC unit and a group A FFP unit. To limit donor exposure, some experts use group O whole blood in this setting, although group O donors with high anti-A titers should be excluded.

WB units or RBC units for large volume transfusions should be relatively fresh, i.e. not >5 to 7 days old. The main reason for this precaution is the high potassium concentration in stored WB or RBC units.

Pretransfusion Testing³⁸

- Source of blood
- Donor
- For blood group compatibility

Donor sample: ABO and RhD groups, antibody screen

Neonatal sample: ABO and RhD groups, DAT, antibody screen if maternal sample not available

Maternal sample: ABO and RhD groups, antibody screen

Guidelines for Red Blood Cell (RBC) Transfusion Thresholds in Preterm Infants^{39,40}

Assisted Ventilation < 28 days

- $\text{FiO}_2 < 0.3$ —Hb < 12 g/dl or PCV < 0.40
- $\text{FiO}_2 > 0.3$ —Hb < 11 g/dl or PCV < 0.35
- ≥ 28 days—Hb < 10 g/dl or PCV < 0.30

CPAP

- < 28 days Hb < 10 g/dl or PCV < 0.30
- ≥ 28 days Hb < 8 g/dl or PCV < 0.25

Breathing Spontaneously

- $\text{FiO}_2 > 0.21$ —Hb < 8 g/dl or PCV < 0.25
- Well, in air—Hb < 7 g/dl or PCV < 0.20

RBC transfusion may be considered at higher thresholds for neonates with hypovolemia, septic shock, NEC, undergoing/ recovering from major surgery.

Role of Erythropoietin (EPO)

Recombinant human EPO may reduce red cell transfusion requirements in neonates. However, its effect appears to be relatively modest and does not reduce transfusion requirements within the first two weeks of life, when sick neonates are most transfusion dependent because of frequent blood sampling. The optimal dose, timing and nutritional support required during EPO therapy has yet to be defined and currently the routine use of EPO in this patient group is not recommended as similar reduction in blood use can probably be achieved by institution of appropriate transfusion protocols.⁴¹⁻⁴³

PLATELET TRANSFUSIONS

- Platelets have to be stored at 20 to 22°C on a constant agitator
- Should be transported quickly and infused over 20 to 30 minutes rapidly
- No glassware to be used
- One should use ABO/Rh identical/compatible donor

Newborns should receive platelet transfusions in similar clinical settings as for older children. However, since newborns frequently manifest thrombocytopenia and since preterm infants are at increased risk for PVH-IVH, it is possible that the platelet level at which prophylactic platelet transfusions should be administered to newborns is higher than that recommended for other patients. The platelet levels at which prophylactic platelet transfusions were given to neonates varied tremendously: from $< 20 \times 10^9/\text{L}$ to $> 50 \times 10^9/\text{L}$ in stable preterm infants and $< 20 \times 10^9/\text{L}$ to $> 80 \times 10^9/\text{L}$ in sick preterm infants. The non-bleeding premature infants with platelet counts $> 60 \times 10^9/\text{L}$ should not receive prophylactic platelet transfusions.⁴⁴

Neonates with thrombocytopenia due to maternal platelet alloantibodies require special consideration with

respect to the indications for platelet transfusion. These neonates require HPA-compatible platelets in addition to high dose IVIG. In these patients, a minimum platelet count of $30 \times 10^9/\text{L}$ is recommended.

What to do in an Emergency?

- Is there a role of Rh immunoglobulin prophylaxis?
- Platelet transfusion is common in neonatal intensive care units, occurring in 2 to 9.4 percent of all admissions.⁴⁵⁻⁴⁷
- Most platelet transfusions are given prophylactically to non-bleeding neonates.
- More than half of neonates given platelet transfusions receive more than one transfusion, with a significant proportion receiving more than four transfusions.⁴⁵⁻⁴⁷
- Thrombocytopenic neonates who receive platelets are up to 10 times more likely to die than neonates who do not receive platelet transfusion (Table 1).

TYPES OF PLATELETS³⁹

Random Donor Platelets

- Also called platelet pack and derived from a single unit of whole blood.
- Contains $5-6 \times 10^{10}$ platelets in 50 to 60 ml plasma per pack.
- In a newborn 5 to 10 ml/ kg will raise platelet counts to 75,000 to 1,00,000/mm³

Single Donor Platelets³⁹

- Also called platelet concentrate
- Obtained by apheresis

What is the Advantage of SDP?

- It contains $2-3 \times 10^{11}$ platelets in 50 to 70 cc of plasma.
- It has 6 to 7 times more platelets than RDP.
- In a newborn infant, small aliquots can be used from an RDP pack or one SDP pack can be used for 3 to 4 newborn babies.

Dose of Platelet Transfusion⁴⁹

- In small children (< 20 kg), 10 to 15 ml/ kg up to the adult dose of one platelet concentrate is used.
- The dose of platelets ($\times 10^9$) can be calculated in more detail, if required, from the desired platelet increment (PI), the patient's blood volume in liters and a correction factor (F) of 0.67.

Platelet Transfusion Efficacy⁵⁰

- Platelet recovery: The percentage platelet recovery (R) is calculated from the platelet increment ($10^9/\text{L}$) (PI), the blood volume (BV) in liters and the platelet dose transfused (10^9) (PD):
- $\text{R\%} = \text{PI} \times \text{BV} \times \text{PD}^{-1} \times 100$

Table 1: Guidelines for platelet transfusion thresholds for neonates⁴⁸

Platelet ($\times 10^9/l$)	Non-bleeding neonate	Bleeding neonate	Auto-ITP	NAITP (proven or suspected)
<30	Consider transfusion in all patients	Transfuse	Transfuse if bleeding present or IVIG unavailable	Transfuse (with HPA compatible platelets) if bleeding
30–49	Do not transfuse if clinically stable Consider transfusion if: <1000 g and <1 week of age Clinically unstable (e.g. fluctuating BP) Previous major bleeding tendency (e.g. grade 3–4 IVH) Current minor bleeding (e.g. petechiae, puncture site oozing) Concurrent coagulopathy Requires surgery or exchange transfusion	Transfuse	Do not transfuse if stable and not bleeding	Transfuse (with HPA compatible platelets) if bleeding
50–99	Do not transfuse	Transfuse	Do not transfuse	Transfuse (with HPA compatible platelets) if major bleeding
>99	Do not transfuse	Do not transfuse	Do not transfuse	Do not transfuse

- The corrected count increment ($10^9/l$) (CCI) is calculated from the corrected count increment (PI), the body surface area of the patient in square meters (BSA) and the dose of platelets transfused (10^{11}) (PD):
- $CCI = PI \times BSA \times PD^{-1}$

Giving Sets/Filters for Platelet Transfusion⁴⁹

- Platelet concentrates should be transfused through a standard blood or platelet administration set.
- Platelet concentrates should not be transfused through giving sets that have been used for blood.
- A screen filter is required for the giving of platelets via a syringe in the setting of neonatal or fetal transfusion.

Platelets for Neonatal Use

- Components should be free of clinically significant irregular blood group antibodies, including high titer anti-A and anti-B.
- Components should be negative for CMV.
- May be prepared by splitting an apheresis platelet pack (often into four), using a closed system.
- Components should contain $>40 \times 10^9/L$ platelets. Additional labeling is required: *Platelets for neonatal use*.

PLASMA AND ITS DERIVATIVES

Major plasma derivatives which are used are:

- Fresh frozen plasma (FFP)
- Cryoprecipitate
- Hepatitis B Ig

Fresh Frozen Plasma

Traditionally fresh frozen plasma (FFP) has been administered to neonates for a variety of reasons:

- Treatment of proven or suspected disseminated intravascular coagulation (DIC)
- Prevention of IVH
- Volume replacement
- During sepsis (addition of opsonising factors)
- During episodes of thrombocytopenia
- To “correct” prolonged indices of coagulation (unaccompanied by clinical signs of bleeding or other laboratory findings consistent with DIC—for example, thrombocytopenia or RBC fragmentation).

Except for treatment of DIC (which may also require the administration of cryoprecipitate or specific clotting factors), there is no evidence to support the use of FFP in the other clinical situations listed above.⁵¹

The only indications for FFP in neonates recommended in the recent BCSH guidelines and supported by evidence are:^{52–54}

- DIC
- Vitamin K dependent bleeding
- Inherited deficiencies of coagulation factors.

In VKDB life-threatening bleeding may require FFP treatment or in rare situations treatment with coagulation factor concentrates. Other possible scenarios where its use may be considered are:

- Reversal of pro-coagulant drug effect
- Invasive procedures in a baby with PT/PTTK 1.5 to 2 times normal
- To prepare reconstituted whole blood where this product is indicated

The use of FFP has been advocated for prevention of periventricular-intraventricular hemorrhage (PVH-IVH) in the preterm infant, but the current evidence does not support the routine use of prophylactic FFP in preterm infants at risk for PVH-IVH. Also, FFP should not be used as a fluid for hematocrit adjustment in erythrocyte transfusions nor as a replacement fluid in partial exchange transfusion for the treatment of neonatal hyperviscosity syndrome.

Dosage and Administration

When FFP is given for coagulation factor replacement, the dose is 10 to 20 ml/kg. This dose will usually raise the level of coagulation factors by 20% immediately after infusion. Post-transfusion monitoring of the patient's coagulation status (PT, APTT and/or specific coagulation factor assays) is important for optimal treatment.

Cryoprecipitate Transfusion

- The most inexpensive factor VIII concentrate is cryoprecipitate
- 250 ml of fresh plasma yields 1 bag of cryoprecipitate
- It contains 75 to 125 units of Factor VIII
- One bag/ 5 kg body weight raises the recipient's level by 50 percent
- Other indications: Afibrinogenemia/ hypofibrinogenemia/ VWD deficiency

PLASMA PRODUCT TRANSFUSION REACTIONS

- Acute hemolytic transfusion reactions (rare)
- Non-hemolytic transfusion reactions
- Ancillary effects of transfusion
- Graft versus host disease
- Infection

GRANULOCYTE TRANSFUSIONS

Newborns normally have a transient neutrophilia in the first week of life with mean normal absolute neutrophil counts ranging from $11.0 \times 10^9/L$ at birth to $5.5 \times 10^9/L$ this age.⁵⁵ Septic newborns frequently develop neutropenia, defined in the newborn as an absolute neutrophils count below $3.0 \times 10^9/L$. Between 1981 and 1992, 5 controlled trials of granulocytes transfusions for septic newborns with neutropenia were reported and have recently been reviewed.⁵⁶ The data suggest a beneficial role for granulocyte transfusion provided an adequate dose is administered. Nevertheless, the use of granulocyte transfusions for neonatal sepsis has not become widespread, possibly because of the difficulty of obtaining granulocytes as rapidly as would be required in this setting. More recently, investigators in the field have begun to study the role of G-CSF in the treatment of neonatal sepsis.⁵⁷

For neonates and small children, a daily infusion of 1×10^9 PMN's/kg should be given and for larger patients, $2-3 \times 10^{10}$ PMNs. As there is significant RBC contamination, units must be ABO compatible and if possible RhD negative for RhD-negative recipients and must undergo the usual compatibility testing. Because most patients receiving these products are severely immunosuppressed, apheresis granulocytes are usually irradiated to prevent TA-GVHD.

SPECIAL TOPICS

Transfusion in Necrotizing Enterocolitis

Infants with necrotizing enterocolitis (NEC) may occasionally be systemically infected with neuraminidase-producing organisms, such as *Clostridium* spp. Neuraminidase can strip sialic acid residues from red cell sialoglycoproteins exposing the T-crypto antigen; a state commonly known as 'T-activation'. T-activation can be detected simply and rapidly using a commercial lectin panel. Adult (but not neonatal plasma) almost invariably contains anti-T, a potentially hemolytic IgM antibody. There is currently no consensus either with respect to the frequency of T-activation or the clinical significance of this finding in infants with NEC.^{58,59} It is recommended that patients with NEC be transfused with red cells in SAG-M as this is relatively plasma-free. Platelets, FFP and/or cryoprecipitate should only be administered when clearly indicated. Any patient with NEC who develops hemolysis, should be investigated to determine the cause of this. This should include a lectin test to look for T-activation. If T-activation is the likely cause, then an ET may be necessary. There is support but no consensus for routine provision of 'low-titer anti-T' plasma and platelet product for patients with T-activation. Access to these rare products is limited.

Exchange Transfusion in Neonates

Exchange transfusion (ET) may be used to manage severe anemia at birth, particularly in the presence of heart failure, and to treat severe hyperbilirubinemia, usually caused by HDN. Controversial indications such as metabolic disease, septicemia and DIC have not been subjected to adequate clinical evaluation.

It is a specialist procedure associated with a potential for serious adverse events. While there is no consensus amongst neonatologists, plasma reduced red cells with a hematocrit (Hct) of 0.50 to 0.60 should be suitable for both hyperbilirubinemia and severe anemia.

Hemolysis may develop in fetuses and neonates who are ABO incompatible with their mother. Clinically significant hemolysis generally occurs only if the mother is group O and the infant group A (occasionally in group B babies). The hemolysis is due to the IgG anti-A or anti-B crossing the placenta and binding to the fetal red cells.

If an ET is required in ABO HDN, this should be with group O red cells with low titer plasma anti-A and anti-B, or with group O red cells suspended in AB plasma.

Exchanging the estimated volume of the baby's blood in a "single volume exchange" will remove 75 percent of red cells, while a "double volume exchange" (160 to 200 ml/kg, depending on gestation) removes 90 percent of the initial red cells. A double volume exchange can remove 50 percent of available intravascular bilirubin.

Red cells for ET should be:

- Group O or ABO compatible with maternal and neonatal plasma, RhD negative (or RhD identical with neonate)
- Negative for any red cell antigens to which the mother has antibodies
- IAT- cross match compatible with maternal plasma
- 5 days old or less
- Collected into CPD anticoagulant
- CMV seronegative
- Irradiated and transfused within 24 hrs of irradiation.

Calculations for neonatal exchange transfusion

- Two-volume red cell exchange transfusion for treatment of sickle cell crisis and neonatal hyperbilirubinemia
- Replace calculated blood volume with whole blood or red cells suspended in 5 percent human albumin
- Volume to be exchanged (ml):

$$[\text{Estimated blood volume} \times (\text{Patient's hematocrit (\%)} \times 2)] / \text{Hematocrit of transfused unit (\%)*}$$

* Hematocrit

Whole blood 35 to 45 percent

Red cell concentrates 55 to 75 percent

Red cell suspension 50 to 70 percent

Intrauterine Transfusion (IUT)⁶⁰

IUTs are usually administered only in specialized units. Red cell IUT is indicated to correct fetal anemia caused by red cell alloimmunization (most important antigen-RhD followed by RhC and K) or, less commonly, for fetal parvovirus infection. Platelet IUTs are indicated to correct fetal thrombocytopenia caused by platelet alloimmunization. The aims of IUT are (i) to prevent or treat fetal hydrops before the fetus can be delivered and (ii) to enable the pregnancy to advance to a gestational age that will ensure survival of the neonate (in practice, up to 36 to 37 weeks) with as few invasive procedures as possible (because of the risk of fetal loss). This is achieved by (i) starting the transfusion program as late as safely possible but before hydrops develops and (ii) maximizing the intervals between transfusions, by transfusing as large a volume of red cells as is considered safe.

COMPONENT AND PROCEDURE SPECIFICATION

Red Cells Preparations

Red cells preparations for IUT should:

- Be group O (low titre hemolysin) or ABO identical with the fetus (if known) and RhD negative. K-negative blood is recommended to reduce additional maternal alloimmunization risks. In exceptional cases, e.g. for hemolysis because of maternal anti-C, it may be necessary to give RhD positive, C-negative blood;
- Be IAT-cross-match compatible with maternal serum and negative for the relevant antigen(s) determined by maternal antibody status;
- Be <5 day old and in citrate phosphate dextrose (CPD) anticoagulant;
- Be CMV seronegative;
- Be irradiated;
- Have a hematocrit (packed cell volume, PCV) between 0.70 to 0.85;
- Not be transfused straight from 4°C storage. Any active warming must be carried out with great care and the blood product not exposed to temperatures higher than 30°C. Active warming may not be necessary if the infusion is conducted carefully and at an appropriate rate (see below);
- Be in a volume calculated from the formula of Rodeck and Deans (1999);
- $(\text{Desired PCV} - \text{Fetal PCV} / \text{Donor PCV} - \text{Desired PCV}) \times \text{Fetoplacental BV}$; where BV is blood volume;
- Be transfused at a rate of 5 to 10 ml/min.

Platelet Preparations

Platelet Preparations for IUT should

- Be group O RhD negative and test negatively for high-titre anti-A or anti-B (i.e. have a low titre hemolysin) or group specific/compatible with maternal antibody;
- Be human platelet-specific alloantigen (HPA) compatible with maternal antibody;
- Preferably be collected by apheresis. A platelet concentrate derived from whole blood donations is less preferred;
- Be irradiated;
- Be concentrated to a platelet count of at least $2000 \times 10^9/\text{L}$;
- Be warmed, if warmed at all, with extreme care. As the ambient temperature for storing platelet concentrates is 22°C, and as the recommended rate of infusion (see below) is slower than that for red cells, active warming may not be needed. If it is conducted, it should not be beyond 30°C;
- Be in a volume calculated from the formula:

$$(\text{Desired platelet increment} / \text{Platelet count of concentrate}) \times \text{Feto-placental BV}$$

- Be transfused at a rate of 1 to 5 ml/min (transfused more slowly than red cells because of the increased risk of fetal circulatory stasis and asystole).

Compatible platelets should be available at the time of diagnostic fetal sampling for alloimmune thrombocytopenia, even if the primary purpose is not that of transfusion, because in the presence of severe fetal thrombocytopenia, fetal hemorrhage can be prevented by platelet transfusion.

Guidelines at Sir Ganga Ram Hospital (SGRH)

RBC Transfusion Guidelines

- Transfuse infants at hematocrit <20 percent or hemoglobin <7 gm/dl even if asymptomatic.
- Transfuse infant at hematocrit <30 percent or hemoglobin <10 gm/dl
 - On minimal mechanical ventilation <35 percent O₂ under hood
 - If significant apnea with bradycardia (2 episodes in 24 hrs requiring bag and mask ventilation) while receiving therapeutic doses of methylxanthines)
 - If heart rate >180/min or respiratory rate >80/min persisting for 24 hours
 - If weight gain of <10 gm/day is observed over 4 days while receiving >100 kcal/kg/day
 - If undergoing surgery
- Transfuse packed red blood cells for hematocrit <35 percent and hemoglobin <12 gm/dl
 - If receiving more than 35 percent supplemental O₂ under hood
 - If on significant mechanical ventilation, MAP >6 cm water

Platelet Transfusion Guidelines

Prophylactic Platelet Transfusion

- Stable preterm neonate with platelet count <30,000
- Stable term neonate with platelet count <20,000
- Sick preterm neonate with platelet count <50,000
- Sick term neonate with platelet count <30,000
- Preparation for invasive procedure—lumbar puncture or minor surgery (central line insertion) with platelet count <50,000
- Major surgery with platelet count <1,00,000

Platelet Transfusion in Neonate with Clinically Significant Bleeding

- Neonate with platelet count <50,000
- Neonate with condition that increases bleeding, e.g. DIC and platelet count <1,00,000
- Neonate with documented platelet function disorder irrespective of circulating platelet count.

Definition of Sick Neonate for Following Guidelines

- Cardiovascular instability, HR >180/min or dopamine or inotropic infusion at >3 mcg/kg/min
- Respiratory instability, FiO₂ requirements >0.4 or significant mechanical ventilation MAP >7
- Central nervous system instability within 72 hours of seizure
- Bleeding neonate meeting the clinical or laboratory criteria for DIC, at discretion of treating physician
- Within 5 days of major surgery
- Preterm neonate with birth weight <1,500 g within first 7 days of life.

Anemia in Newborn

Mohammed Ramzan, SP Yadav, Anupam Sachdeva

INTRODUCTION

Normal erythropoiesis is influenced by several factors, especially erythropoietin (EPO), which stimulates maturation of red blood cell (RBC) precursors. Neonatal Anemia is defined as hemoglobin or hematocrit concentration of >2 standard deviation below the mean for postnatal age. This may be due to three general causes: blood loss, increased RBC destruction or decreased RBC production. The major physiologic impact of anemia is decreased oxygen delivery to tissue, resulting in both compensatory responses and acute or chronic consequences including poor growth, decreased activity and limited cardiovascular reserve. Rapid changes in normal hematological parameters take place throughout the neonatal period. Therefore, the diagnosis of anemia in the newborn is made in relation to gestation and postnatal age. Anemia during 1st week of life is defined as hemoglobin level less than 14 gram/dl or Hct <45 percent in a term infant. Any significant fall in hemoglobin in a neonate, although, within normal range is suggestive of hemorrhage or hemolysis. For example, in a term newborn whose hemoglobin was 18.0 gram/dl at birth, hemoglobin of 14.0 gram/dl on D7 of life is abnormal. Similarly, failure of hemoglobin to rise during first few hours of life may be the first clue to a hemorrhage or hemolysis in a newborn. Severe anemia present at birth (i.e. Hemoglobin <8.0 gram/dl) is usually due to immune hemolysis or hemorrhage.

FETAL ERYTHROPOIESIS

Fetal erythropoiesis occurs in yolk sac, liver and bone marrow as gestation progresses. It originates initially between 10 to 14 days of gestation in yolk sac. By 6 to 8 weeks of gestation more definitive fetal erythropoiesis is taking place in the liver. The liver remains the primary site of erythroid

production throughout the early fetal period. By 6 months of gestation bone marrow becomes the principal site of erythroid development. At later part of gestation erythropoietin switches from less sensitive hepatic to the more sensitive renal site. The major difference between fetal and adult erythropoiesis is in the response to erythropoietin. Erythropoietin response is poor in newborns especially in premature neonates and it persists through the neonatal period, resulting in a reduced erythropoietic stimulus and lower hemoglobin levels. The erythroid blood cell indices change during gestation and continue to change throughout infancy. The red cell values on the first postnatal day during the last 16 weeks of gestation is shown in Table 1.

NORMAL HEMATOLOGICAL VALUES IN NEONATAL PERIOD

RBC values are more variable in neonatal period, than any other time of life and understanding of normal values of hemoglobin and other red cell indices is essential for diagnosing anemia in newborn (Tables 2 and 3).

Causes of Neonatal Anemia

Anemia in neonatal period is mainly due to three distinct causes:

- Blood loss/hemorrhage: Acute/chronic, prenatal/natal/ postnatal
- Hemolysis: Immune/non-immune
- Failure of red cell production

Blood Loss

It is the most common cause of neonatal anemia. It includes:

- Obstetrical causes
- Fetomaternal transfusion

Table 1: Red blood cell values on the first postnatal day

	<i>Gestational Age (Weeks)</i>							
	24–25 (7)	26–27 (11)	28–29 (7)	30–31 (35)	32–33 (23)	34–35 (23)	36–37 (20)	Term (19)
RBC count ($10^6/\text{mm}^3$)	4.65 ± 0.43	4.73 ± 0.45	4.62 ± 0.75	4.79 ± 0.74	5.0 ± 0.5	5.09 ± 0.5	5.27 ± 0.68	5.14 ± 0.7

12–18 hours	108.96 ± 5	35.1 ± 1.9	34.4 ± 0.6	283 ± 122
72 hours	98.54 ± 2.9	35.82 ± 0.8	34.9 ± 0.5	36 ± 48
7 days	96.0 ± 3.4	34.0 ± 1.0	34.6 ± 0.8	
15 days	95.5 ± 4.0	33.2 ± 9.0	34.54 ± 0.5	
28 days	96.1 ± 3.2	31.6 ± 0.93	34.2 ± 0.7	

- Fetoplacental transfusion
- Twin-twin transfusion
- Internal hemorrhage
- Iatrogenic blood loss

Increased RBC Destruction

- Intrinsic causes: Hereditary RBC disorders (rare), including:
 - RBC Enzyme defects (e.g. G6PD deficiency)
 - RBC membrane defects (e.g. hereditary spherocytosis)
 - Hemoglobinopathies (e.g. α -thalassemia)
- Extrinsic causes:
 - Immune hemolysis
 - Rh incompatibility
 - a. ABO incompatibility
 - b. Minor blood group incompatibility (e.g. Kell, Duffy)
 - c. Hemangiomas (Kasabach-Merritt syndrome)
- Acquired hemolysis:
 - Infection
 - Vitamin E deficiency (of historical interest, now it is very rare)
 - Drugs

Decreased RBC Production

- Anemia of prematurity due to transient deficiency of erythropoietin
- Aplastic or hypoplastic anemia (e.g. Diamond-Blackfan)
- Bone marrow suppression (e.g. with Rubella or Parvovirus B₁₉ infection)
- Nutritional anemia (e.g. iron deficiency), usually after neonatal period.

Hemorrhage

About 5 to 10 percent of the cases of severe neonatal anemia are due to hemorrhage and this may occur during prenatal, intranatal or postnatal period. Blood loss may be the result of occult hemorrhage before birth, obstetric accidents, internal hemorrhage, or excessive blood sampling for diagnostic studies. In an anemic newborn not having jaundice and a negative Coombs test, hemorrhage is the most probable cause (Table 4).

Prenatal Blood Loss

Transplacental fetomaternal blood loss: Spontaneous leakage of small amount of fetal Hb into maternal circulation occurs in 50 percent of all pregnancies, but in about

Table 4: Types of hemorrhage in the Newborn Period

<i>Occult Hemorrhage before Birth</i>	<i>Obstetric Accidents and Malformations</i>	<i>Internal Hemorrhage</i>
<ul style="list-style-type: none"> Fetomaternal Traumatic amniocentesis Spontaneous After external cephalic version Twin to twin 	<ul style="list-style-type: none"> Nuchal cord with placental blood trapping Rupture of normal umbilical cord Precipitous delivery Entanglement Hematoma of the cord or placenta Rupture of abnormal umbilical cord- Varices, aneurysm Rupture of anomalous vessels Aberrant vessel Velamentous insertion Vessels in multilobed placenta Incision of placenta during cesarean section Placenta previa abruptio placentae 	<ul style="list-style-type: none"> Intracranial Giant cephalohematoma Subgaleal Retroperitoneal Laceration of the liver Ruptured spleen Pulmonary

1 percent it is of sufficient magnitude to produce anemia in the infant. In general, a loss of 20 percent of the blood volume acutely is sufficient to produce signs of shock and is reflected in a fall in hemoglobin concentration within 3 hours. The frequency and magnitude of fetomaternal hemorrhage is increased by invasive procedures like amniocentesis and external cephalic version. Fetomaternal bleed is diagnosed by demonstrating fetal red cells in the maternal circulation by Kleihauer–Betke technique (Acid elution method of staining for fetal hemoglobin). But in presence of thalassemia minor, sickle cell anemia, hereditary persistence of fetal hemoglobin Kleihauer Betke test is not useful. In such cases differential hemagglutination should be employed. Similarly in ABO blood group incompatibility, diagnosis may be missed as infant's A or B cells are rapidly cleared from maternal anti-A or anti-B. The amount of blood lost in fetomaternal hemorrhage can be calculated by following formula:

$$\text{ml. of fetal blood} = \frac{\text{Fetal RBC} \times 2400}{\text{Maternal RBC}}$$

Presence of 1 fetal RBC per 1000 maternal RBC's indicates 2 ml of fetomaternal hemorrhage.

Transplacental bleed may be acute or chronic. The characteristics of acute and chronic blood loss in a newborn are listed in Table 5.

Retroplacental Bleed

Abnormally implanted placenta and placental malformation can cause retroplacental bleed. This can be diagnosed by examination of placenta in an anemic newborn. Accidental incision of the placenta during cesarean section can also cause massive fetal hemorrhage.

Twin to Twin Transfusion

In 13 to 33 percent of mono-chorionic twins, significant twin to twin transfusion occurs. This condition should be suspected if there is difference of hemoglobin of over 5 gram/dl between the twins. There is maximal discrepancy of 3.3 g/dl in cord hemoglobin in dizygotic twins. Typically

Table 5: Characteristics of acute and chronic blood loss in the neonate

<i>Acute blood loss</i>	<i>Chronic blood loss</i>
Pallor	Pallor
Shallow tachypnea	Signs of cardiac failure
Poor peripheral perfusion	Cardiac enlargement
Hypotension	Tachypnea
No organomegaly	Hepatomegaly
Normochromic microcytic anemia	Ascites
	Hypochromic, microcytic anemia
	Reticulocytosis

the donor twin is smaller, pale and may show evidence of heart failure, hydrops and shock. The recipient twin is larger and polycythemic and may manifest signs and symptoms of hyperviscosity syndrome, disseminated intravascular coagulation and hyperbilirubinemia.

Postnatal Blood Loss

Anemia that appears in first 24 to 72 hours of life and is not associated with jaundice is commonly caused by hemorrhage at the time of birth or by a postnatal hemorrhage. One of the commonest causes of obvious bleeding in the newborn is slipped ligature of the cord. Traumatic delivery, especially forceps and breech delivery, results in subgaleal (scalp) intracranial or intra-abdominal hemorrhage. An infant with internal bleed may appear well for first 24 to 48 hours, but may then suddenly go into shock. Hemophilia, vit. K deficiency and disseminated intravascular coagulation are also important causes of postnatal bleed.

Iatrogenic Anemia

Frequent sampling for diagnostic and monitoring purposes in neonatal critical care unit is a common cause of anemia in newborn, especially in the preterm babies. Removal of more than 20 percent of a subject's blood

volume produces anemia. 1 ml of blood represents about 1 percent of total blood volume in preterm babies. In a 1500 gram baby this represents a blood loss of only 25 to 30 ml. Thus, excess sampling should be avoided.

HEMOLYTIC ANEMIA

Premature destruction of RBC leads to hemolytic anemia. Hemolysis as a cause of anemia should be suspected in presence of rapid fall of hemoglobin concentration with reticulocytosis, unconjugated hyperbilirubinemia and hemoglobinuria without any evidence of hemorrhage. Abnormal erythrocyte morphology also points towards hemolytic process. Hemolysis can be due to immune mediated or non-immune mediated mechanism. Non-immune hemolytic anemia involves defects in either red cell membranes or hemoglobin or enzyme defects.

Nonimmune Mediated Hemolytic Anemia

- *Red cell membrane defects* such as hereditary spherocytosis, elliptocytosis stomatocytosis can cause significant anemia in newborn. A family history of chronic anemia, cholelithiasis, unhealed leg ulcers, splenomegaly may be present in case of hereditary spherocytosis. Examination of peripheral blood smear and osmotic fragility test is diagnostic in hereditary spherocytosis.
- *Hemoglobinopathies*: Defect or deficiency of production of globin chains results in hemolytic anemia. In the newborn period, α -globin defect tends to be the most common and most severe, because γ chain defects are exceedingly rare and β chain production does not usually peak until about 3 months of age. Homozygous alpha thalassemia is due to absence of all four alpha globin chains and is associated with severe intrauterine hemolytic anemia, hydrops fetalis with massive hepatosplenomegaly. Most affected children are stillborn, although some may live for few hours after birth. The red blood cell in alpha thalassemia is hypochromic, fragmented and bizarre in shape and erythroblastosis is also seen.

Gamma thalassemia: Large deletion within the beta globin gene cluster sometimes removes both gamma globin chains as well as delta and beta globin chain. The resulting gamma-delta-beta thalassemia is lethal in the homozygous state. In heterozygous state, it produces a transient but moderate to severe anemia but this anemia improves spontaneously within first six months of life and afterwards the hematological picture is like thalassemia trait.

RBC enzyme abnormalities: Most commonly encountered enzymopathy in newborn is sex-linked G-6PD deficiency and others are pyruvate kinase deficiency, 5' nucleotidase deficiency and glucose phosphate isomerase deficiency. In India G-6PD deficiency is common in Parsi, Bhanushali, Sindhi

and Punjabi communities. It can cause significant neonatal hemolysis resulting in anemia and hyperbilirubinemia due to exposure to known hemolytic agent and cases have been seen without any exposure to oxidant or infection. Normal value of G-6PD level during acute hemolysis may not rule out G-6PD deficiency as younger RBC's contain high level of enzyme. Hence, G-6PD level should be repeated after 6 weeks of an episode of hemolysis.

Infection: Both prenatal and postnatal infections cause anemia and other hematological abnormalities in the neonatal period. Intrauterine infections of *Toxoplasma*, cytomegalovirus, syphilis, rubella, malaria and parvovirus (TORCH) can cause hemolysis. The hemolytic process is due to direct injury to the red cell membrane. Congenital infection is suspected due to clinical findings of chorioretinitis, pneumonitis, central nervous system abnormalities, hepatosplenomegaly, growth retardation and skin changes. If the spleen is enlarged, hypersplenism can increase the rate of red cell destruction. Laboratory features include thrombocytopenia, leukocytosis with immature form and reticulocytosis. Postnatal acquired infection produce marrow suppression and hemolysis of RBC thereby causing anemia in newborn. Vertical transmission of malaria is rare. Features of malaria in a newborn are fever, irritability, hepatosplenomegaly with severe anemia and reticulocytosis.

Immune Mediated Hemolytic Anemia

The immune causes are mainly due to blood group incompatibility between fetus and the mother. This incompatibility may be Rh (D), ABO or minor blood groups such as anti-C, Duffy, anti-C, anti-E, Kell, etc.

- *Rh isoimmunization*: Placental transfer of maternal antibodies directed against fetal RBC is the cause of hemolysis of neonatal RBC. Clinical features of Rh isoimmunization are anemia, which may be mild to severe, jaundice, hepatosplenomegaly. Laboratory investigations reveal blood group incompatibility, reticulocytosis and increased number of nucleated RBC's in peripheral blood smear and positive direct Coombs test.
- *ABO incompatibility*: In ABO incompatibility, maternal Anti-A or Anti-B antibodies enter fetal circulation and react with A or B antigen on the erythrocyte surface. ABO incompatibility frequently occurs during first pregnancy without prior sensitization. Hemolysis due to ABO incompatibility is clinically milder than Rh incompatibility but severe hemolysis occurs occasionally. In most cases pallor and jaundice are minimal and hepatosplenomegaly is uncommon. Direct Coombs test is frequently negative but indirect Coombs test is positive. On peripheral smear, spherocytes are found so it is sometimes confused with hereditary spherocytosis.

Failure of Red Cell Production

Congenital

Pure red cell aplasia (Diamond Blackfan anemia), congenital sideroblastic anemia, congenital dyserythropoietic anemia (CDA), Fanconi's anemia are some of the causes of congenital anemia in newborn. Diamond Blackfan syndrome is characterized by the absence of recognizable erythroid precursor cells in bone marrow. Physical abnormalities associated with Diamond Blackfan syndrome are triphalangeal or duplicated thumb, cleft palate, ocular defect, short or webbed neck, hypertelorism, ptosis. Diagnosis is confirmed by demonstrating virtual absence of erythroid precursors in bone marrow. Fanconi's anemia usually does not manifest in the newborn period. Most patients of CDA are diagnosed in late childhood or adolescence, however some present in neonatal period with variable splenomegaly, jaundice and normocytic normochromic anemia.

Anemia of Prematurity

All infants experience a decrease in hemoglobin concentrations after birth, as the infant transitions from a relatively hypoxic state *in utero* to a relatively hyperoxic state in room air. Increased tissue oxygenation leads to a decline in erythropoietin (EPO) concentration and, for the term infant, a physiologic and usually asymptomatic anemia at age 8 to 12 weeks. Anemia of prematurity (AOP) is an exaggerated and pathologic response of the preterm infant to this transition. AOP is a normocytic, normochromic, hyporegenerative anemia that is characterized by the existence of a low serum EPO level in an infant who has what may be a remarkably reduced hemoglobin concentration. AOP results from a combination of relatively diminished RBC production, shortened RBC life span, and blood loss. Frequent sampling, low level of hematopoietic growth factors such as insulin like growth factor-1 and 2, nutritional deficiencies of iron, vitamin E, vitamin B₁₂, and folate may exaggerate the degree of anemia. The frequency of anemia of prematurity (AOP) is inversely related to the gestational age and/ or birth weight of the population. As many as 50 percent of infants of less than 32 weeks gestational age develop symptoms as a result of AOP. AOP spontaneously resolves by the time most patients are aged 3-6 months. Although the physiology and pathophysiology for AOP are well studied, controversy surrounds the timing, method, and effectiveness of therapeutic interventions for AOP. In term infant the hemoglobin level reaches its nadir of 9 to 11 gm/dL at approximately 8 to 12 weeks of life. The more immature the infant, the more is the likely development of AOP. AOP is not typically a significant issue for infants born beyond 32 weeks' gestation. The nadir of the hemoglobin level is typically observed when the tiniest infants are aged 4 to 8 weeks, with concentrations of 8 to 10 g/dL if birth weight was 1200 to 1400 gm, or 6 to 9 g/dL if birth weight was less than 1200 gm. Clinically these infants may

have tachycardia, tachypnea, feeding problems, decreased activity and apneic attacks. The factors operating in physiological anemia of term baby is also present in preterm baby, but are exaggerated. The response to anemia or hypoxia to hepatic erythropoietin synthesis in preterm baby is poor as compared to that in term baby. Early administration of iron (2-4 mg/kg/d) does not modify the course of early physiological anemia of prematurity but would prevent the occurrence of late physiological anemia at around 6 months of age. Anemia of prematurity is treated with recombinant human erythropoietin. The dose of erythropoietin is 75 to 300 units/kg/week subcutaneously for 4 weeks starting at 3 to 4 weeks of age.

Diagnostic Approach to Anemia in a Newborn

Medical history and physical examination can give a lead to the cause of anemia in a newborn. Family history of anemia, cholelithiasis, unexplained jaundice and splenomegaly points toward some hereditary hemolytic anemia. Obstetric history of difficult labor, instrumentation, bleeding or placental abnormalities correlate with hemorrhagic anemia. The age at which anemia becomes manifest also is of diagnostic importance. Significant anemia at birth is due to blood loss or alloimmunization. After 24 hours, internal hemorrhage and other causes of hemolysis manifest. Anemia of prematurity, hypoplastic anemia and abnormalities of synthesis of hemoglobin chain generally appear several weeks after birth.

Coombs test, reticulocyte count, mean corpuscular volume (MCH) and blood smear are the key investigative tools for diagnosing the cause of anemia in newborn. Flow chart 1 shows a flow diagram of investigation of anemia in newborn.

Prevention and Treatment of Anemia in Newborn

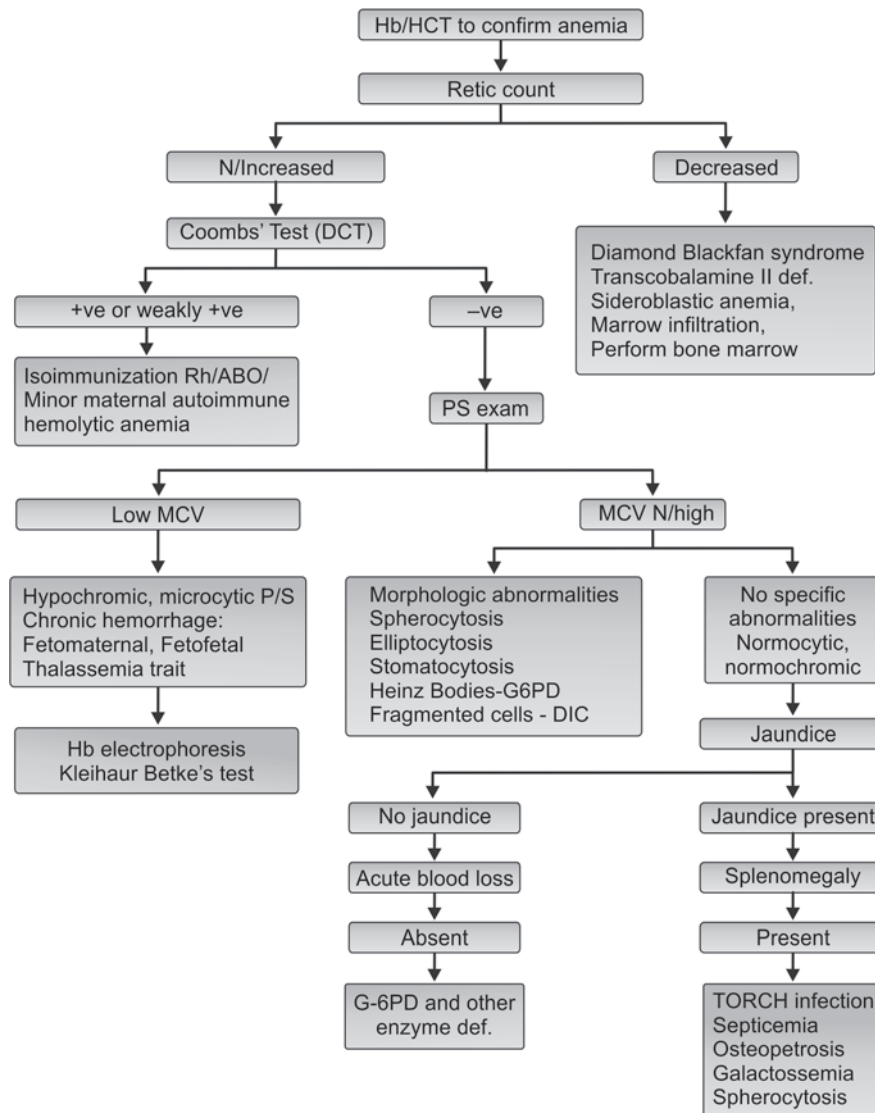

Prevention

In physiological anemia observed in infants born at term, the hemoglobin remains stable for several weeks and then increases progressively. Physiological anemia often presents without signs, and there is no need for RBC transfusions. In contrast, anemia of prematurity develops earlier (i.e. at four to 12 weeks of life) and may present with clinical signs such as tachycardia. In sick preterm infants, anemia of prematurity can be accentuated by non-physiological anemia. The most common cause of non-physiological anemia is blood loss, which may be acute or chronic. A common and potentially avoidable cause of postnatal blood loss is iatrogenic as a result of frequent blood sampling (phlebotomy) in sick preterm infants.

To prevent and reduce the severity of anemia, and to reduce donor exposure or the risks associated with RBC transfusions, strategies to consider may include:

- Delayed clamping of the umbilical cord;
- Restricting blood sampling;

Flow chart 1: Approach to neonatal anemia

- Using recombinant human erythropoietin to stimulate erythropoiesis;
 - Using iron supplementation or vitamins to minimize the severity of anemia;
 - Using appropriately collected and stored multipack RBC units;
 - Using appropriately screened and handled RBCs from regular or designated donors;
- Collecting and transfusing umbilical cord blood (autologous blood transfusion).

Iron Supplementation

Preterm infants exhibit a wide range of iron status at discharge, depending on their degree of prematurity, amount of transfusion, phlebotomy losses, number of RBC transfusions, bouts of infection, and timing of iron supplementation. Limiting phlebotomy losses and starting iron therapy at 2 weeks (as opposed to 2 months) of postnatal

age might be an effective preventive strategy against subsequent iron deficiency. The American Academy of Pediatrics recommends that preterm infants receive 2 to 4 mg elemental iron/kg per day; infants receiving EPO therapy should receive at least 6 mg/kg per day. After discharge, preterm infants continue to have increased iron needs because of rapid growth rate during the first postnatal year. There is a high rate of iron deficiency in preterm infants fed low-iron formula or breast milk. Recent data suggest that preterm infants with low serum ferritin concentrations might require additional iron supplementation. It might be prudent to supplement formula-fed preterm infants with iron at a dose of 1 mg/kg per day.

Prevention of Late Nutritional Anemia

Both term and preterm infants should be discharged from the hospital on supplemental iron, either as iron-fortified formulas or as an oral supplement of 2 to 3 mg/kg per day

elemental iron for breastfed infants. Enteral iron supplementation is feasible and probably safe in infants with birth weight <1301 g. Iron supplementation can reduce the incidence of iron deficiency and the number of late blood transfusions. Iron deficiency can occur in very low birth weight infants despite early supplementation with iron and should be considered in the case of progressive anemia. Because of their limited body supplies of water-soluble vitamins and their higher protein requirements, it is also prudent to supplement breastfed preterm infants at discharge with a multivitamin supplement containing vitamin B₁₂ and folate. It is important to monitor premature babies, especially after discharge, to diagnose late anemia in neonates.

Treatment of anemia in a neonate depends on the clinical condition. If the infant is in hypovolemic shock due to acute blood loss, 10-20 ml/kg of whole blood cross matched with mother should be transfused immediately through umbilical vein. In case of unavailability of cross-matched blood, O negative blood can be used. Asymptomatic anemic neonate with moderate hemorrhage or chronic blood loss does not require blood transfusion as such. The only therapy required for such a neonate is iron in the dose of 2 mg/kg three times a day for 3 months. Vit B12 and folate should also be supplemented in discharge to breastfed preterm infants. In severe anemia with congestive cardiac failure due to chronic blood loss partial exchange transfusion or packed cell transfusion is the treatment of choice. RBC transfusion is indicated for asymptomatic infant with venous hematocrit <20 percent and absolute reticulocyte count less than 3 percent. In hemolytic anemia main concern is hyperbilirubinemia, which may require phototherapy or exchange transfusion. Infants with ABO incompatibility not requiring an exchange transfusion for hyperbilirubinemia may have protracted hemolysis and may require RBC transfusion several weeks after birth.

In a hemodynamically unstable infant, hyaline membrane disease or severe bronchopulmonary dysplasia, hemoglobin level is maintained at the level of 12 to 14 gram/dl to improve oxygen delivery. Diamond Blackfan syndrome is managed with corticosteroids and blood transfusion. The criteria for transfusion of infants are given in Table 6.

Dose (Volume) of RBCs

In preterm neonates the small amount of research available suggests that large volume (20 ml/kg) RBC transfusions lead to larger rises in Hb and fewer overall transfusions than small volume transfusions (10 ml/kg). This volume of packed RBCs is well tolerated in the vast majority of preterm neonates.

Do not Transfuse

- To replace blood removal for laboratory tests alone or low hematocrit alone.

Table 6: Transfusions guidelines

Transfuse infants at hemoglobin less than 7

- No symptoms and an absolute reticulocyte count <1,00,000 cells/mL (RBC × % reticulocyte count)

Transfuse infants at hemoglobin <8 or less

No mechanical ventilation requirement and one or more of the following present:

- 24 or more hours of tachycardia (HR >180) or volumes if fluid sensitive) tachypnea (RR >80)
- An increased oxygen requirement from the previous 48 h
- An elevated lactate concentration (2.5 mEq/L or more)
- Weight gain <10 g/kg over previous 4 days while receiving 100 kcal/kg per day or more
- An increase in episodes of apnea and bradycardia (10 or more episodes in a 24-h period or 2 or more episodes in 24 h requiring bag-mask ventilation) while receiving therapeutic doses of methylxanthines
- Undergoing some surgery

Transfuse infants at Hemoglobin 10 or less

- Minimal mechanical ventilation requirement (any mechanical ventilation or CPAP > 6 cm H₂O and FiO₂ >0.4)

Transfuse infants at Hemoglobin 11 or less

- Moderate or significant mechanical ventilation requirement (MAP >8 cm H₂O and FiO₂ > 0.4)

Approach to Bleeding in Neonate

Neha Rastogi, SP Yadav, Anupam Sachdeva

INTRODUCTION

Bleeding in the newborn is often a serious problem because of cardiovascular effects associated with a loss of blood and/ or the damaging effects of bleeding on neonatal tissues, especially the brain. Forty years ago, hemorrhagic disease of the newborn occurred in 1 to 2% of newborn babies.¹ With vitamin K administration routinely administered following birth, this problem is now rare in the normal newborn.² Babies in the neonatal intensive care unit (NICU) more commonly have abnormal bleeding or conditions that increase the risk of bleeding (e.g. thrombocytopenia with platelet count less than $100 \times 10^9/L$ occurs in 12 percent of babies in the NICU.³

CLINICAL ASSESSMENT

Bleeding in the newborn may be manifested by signs of shock, anemia, signs related to pressure from 'hidden' bleeding (e.g. intraventricular hemorrhage), or bleeding from the gastrointestinal tract, respiratory system or skin.⁴ With bleeding from the gastrointestinal tract, it is important to distinguish bleeding in the baby from swallowed maternal blood (an Apt test will distinguish fetal from adult hemoglobin).

First important task to do after identifying that the neonate is bleeding is to ensure the cardiorespiratory stability. A diagnosis to aid in more specific management may then be made.

HEMOSTATIC FUNCTIONS IN NEWBORN

Due to physiological immaturity there are both quantitative as well as qualitative differences in hemostatic functions in newborn as compared to older children.

Primary Phase of Hemostasis

- *Capillary fragility:* Though capillary fragility is normal in term infants, it is increased in preterms therefore vasoconstriction following injury is incomplete in them⁵ and hence intracranial hemorrhage is more common in premature babies.
- Platelet count in both term and preterm babies is similar to that in older child. However, platelet function such as adhesion, aggregation and release of factors like ADP and Thromboxane A2 are abnormal. Exact clinical significance of this defective qualitative function is not known.

Secondary Phase of Hemostasis

Coagulation factors are not transferred transplacentally from mother to the baby and hence the values estimated in newborn reflect the synthesis of the various factors in them.⁶

- At term, levels of factors V, VIII, are equivalent to older children and adults and hence if deficiency of these factors is present during newborn period then it suggests inherited factor deficiency in them.⁷
- Levels of factors II, VII, IX, X are decreased more so in preterm babies due to hepatic immaturity and poor availability of Vit. K. Hence hemorrhagic disease of newborn is more common in premature babies.⁷
- Clotting activities of all factors involved in initial activation of intrinsic pathway is decreased in varying degrees in the newborn, i.e. factor XII, XI, preKalliekrien, high molecular weight kininogen. More immature the infant, the lesser is factor XII activity. Reduced concentrations of factor XII, XI are partly responsible for prolongation of activated partial thromboplastin time so commonly observed in low birth weight infants.

- Factor XIII level in cord blood is 50 percent of that in adults, but as only small amount of factor XIII is required for its activation or clot stabilization, this low value in newborns have no clinical significance.⁷

Fibrinolytic Activity

In newborn it is transiently increased as compared to adults or older children. It declines to adult level by 6 hours in term child. Plasminogen levels are only half that of an adult. FDP is normally absent in healthy preterm and term infants. This low level of plasminogen along with physiological deficiency of circulating anticoagulants like antithrombin III, protein-C promotes thrombotic tendencies in neonates.

Neonates are thus susceptible for both hemorrhage and thrombotic tendencies. This paradox is due to a combined deficiency on one hand in coagulation factors and defective platelet function and decreased levels of natural inhibitors of coagulation and fibrinolysis on the other.

Role of Vitamin 'K' in Neonatal Hemostasis

Vitamin 'K' plays a crucial role in neonatal hemostasis. Vit. K is not required for synthesis of factors but is required for gamma carboxylation of glutamic acid residues of the protein precursors of the factors II, VII, IX and X which are synthesized in liver. These protein precursors are termed as PIVKA, i.e., proteins in absence of vitamin K activity. It is only after gamma carboxylation that these proteins acquire the ability to chelate calcium and to be subsequently activated during coagulation. This action of vitamin 'K' is limited in preterm, as precursor proteins themselves are deficient, often below 30 percent of adult value⁷ as immature liver is incapable of optimal synthesis of many of precursor proteins.

ETIOLOGY OF BLEEDING IN NEONATE

Bleeding in a neonate may be due to.^{5,8,9}

- Vascular abnormalities, e.g. in prematurity – intracranial hemorrhage.
- Platelets abnormalities: Quantitative platelet disorders include Immune thrombocytopenic purpura—child born to mother with SLE or ITP. Isoimmune thrombocytopenia—PIA +ve childborn to PIA –ve mother. Qualitative platelet disorders include drugs like aspirin given to mother and inherited disorders of platelet function like Glanzmann's thrombasthenia, Bernard Soulier syndrome.
- Exaggeration of transient deficiency of coagulation factors
 - Hemorrhagic disease of newborn.
- Transitory disturbances of coagulation mechanism as a result of associated systemic disease process, e.g. sepsis, liver disease, DIC, etc.

- Inherited permanent abnormality of coagulation factors, e.g. Hemophilia A & B, Von-Willebrand disease etc.
- Trauma alone or often associated with other factor deficiencies—slipped ligature, cephalhematoma, etc.

AN APPROACH TO THE BLEEDING NEWBORN

One must assess the total clinical setting because the history and clinical examination are as important as the laboratory findings. One must ask about the familial bleeding tendencies, maternal illnesses especially infections, medications both maternal and neonatal and documentation that vitamin K was given at birth.⁸ The general observation whether the child was 'sick' or 'well' at the onset of bleeding is very important. Certain hemorrhagic tendencies occur almost exclusively in 'sick' neonates. (babies with sepsis, shock, hypoxia, acidosis, hypoglycemia). On the other hand, bleeding manifestations in otherwise 'well' infants (normal birth weight, alert, vigorous, no evidence of any systemic disease) are usually due to classic hemorrhagic disease of newborn or immune-mediated thrombocytopenia or isolated clotting factor deficiencies. The physical examination further defines the nature of bleeding disorder. Petechiae or purpura in the skin are more characteristic of thrombocytopenia, while bleeding from injury sites (e.g. circumcision, heel lance) or the gastrointestinal system suggests other coagulation defects.

LABORATORY ASSESSMENT

Laboratory investigation should include an activated partial thromboplastin time (APTT), prothrombin time (PT) (or more commonly international normalized ratio [INR] to standardize for different reagents) and complete blood count with platelet count. Additionally, all sick newborns should have fibrinogen and fibrin degradation products (FDP) measured.⁴ Blood should preferably be taken from a venous site. Capillary samples are more prone to errors, with clotting in samples including platelet clumping. Although blood from an arterial line may be used if measures are taken to minimize heparin contamination and protamine is used to neutralize any heparin that may be present,¹⁰ this should be reserved for situations when other blood samples cannot be obtained.

Coagulation tests should be ordered whenever the cause of bleeding is not clear. Reference values for coagulation tests at varying ages are available. In general, the following are considered abnormal:

- PT 17 s or more
- INR 1.5 or greater
- APTT 60 s or greater (preterm 80 s or greater in first day of life)
- Fibrinogen less than 1.5 g/L
- FDP present
- Platelet count less than $1,00,000 \times 10^9/L$

While an INR 1.4 or less (or normal PT) rules out vitamin K deficiency, abnormalities in APTT without other evidence of DIC may require more detailed investigation. Measuring factor VIII may help distinguish DIC (low) from liver dysfunction (normal or high), although factor VIII may also be congenitally deficient. In many of these situations, consultation with a hematologist with pediatric experience is advisable to guide investigation and management.

Diagnosis and management of maternal thrombocytopenia may include intravenous immunoglobulin (IVIG), steroids and rarely fetal transfusion in an endeavor to minimize potential adverse effects on the fetus, especially intracranial hemorrhage.⁴ While thrombocytopenia in the newborn is relatively common, it is not always associated with bleeding. Thrombocytopenia has varied etiology (Table 1).^{11,12} Diagnosis may be helped by the microscopic examination of platelet size. Large platelets are more indicative of platelet consumption with new large platelets entering the circulation, while only small platelets may indicate disordered bone marrow function.¹¹ Flow cytometry may be used to look for reticulocytes and immunoglobulins on the surface of platelets. If thrombocytopenia

in the baby is otherwise unexplained, a maternal platelet count is useful.¹¹ Alloimmune thrombocytopenia may be suspected on the basis of a low platelet count in the absence of other etiologies or the absence of response to a platelet transfusion. More specific platelet typing and investigation for antiplatelet antibodies may be required. Investigation for uncommon qualitative defects in platelet function requires specialized tests usually in consultation with a hematologist. Table 2 shows the approach to a newborn with bleeding on the basis of physical examination, PT, APTT and platelet count.

VITAMIN K DEFICIENCY BLEEDING

Since the most common cause of a bleeding neonate is Vitamin K deficiency, it needs to be discussed in detail.

The term Hemorrhagic Disease of the Newborn (HDN) was coined by Charles Townsend in 1894 to describe bleeding in the early days of life which was not caused by traumatic delivery or hemophilia.¹³ The different causes of such bleeding were then unknown. HDN later came to mean bleeding due to Vitamin K (VK) deficiency but still implied a condition confined to neonates. The specific term Vitamin K Deficiency Bleeding (VKDB) was therefore adopted by the Perinatal Subcommittee of International Society on Thrombosis and Hemostasis (ISTH). VKDB is defined as bleeding due to inadequate activities of VK-dependent coagulation factors (II, VII, IX, X), correctable by VK replacement.¹³

Diagnostic criteria laid down by ISTH subcommittee are as follows—in a bleeding infant prolonged prothrombin time (PT) together with normal fibrinogen level and normal platelet count is highly suggestive of VKDB. Rapid correction of PT after VK administration is confirmatory.¹³ The subcommittee also added that acarboxy proteins—PIVKA (proteins induced in vitamin K absence)—are

Table 1: Common causes of thrombocytopenia

Increased destruction	Disseminated intravascular coagulation Localized (thrombosis, hemangiomas, necrotizing endocarditis)
Decreased production	Trisomy 13, 18 or 21 Fanconi anemia Syndromes (e.g., Wiskott-Aldrich, thrombocytopenia, absent radius (TAR))
Other or mixed	Rh disease Exchange transfusion Extracorporeal membrane oxygenation

Table 2: Approach to the differential diagnosis of bleeding neonate

<i>Laboratory investigations</i>				
<i>Health status</i>	<i>Platelets</i>	<i>INR (PT)</i>	<i>APIT</i>	<i>Possible diagnosis</i>
Sick	↓	↑	↑	Disseminated intravascular coagulation (usually low factor VIII)
	↓	N	N	Platelet consumption (infection, necrotizing enterocolitis, renal vein thrombosis)
	N	↑	↑	Liver disease, heparinization (usually normal factor VIII)
	N	N	N	Altered vascular integrity (e.g. extreme prematurity, severe hypoxia and acidosis)
Healthy	↓	N	N	Immune thrombocytopenia, occult infection or thrombosis, abnormal bone marrow function
	N	↑	↑	Hemorrhagic disease of the newborn (vitamin K deficiency)
	N	N	↑	Hemophilia
	N	N	N	Bleeding due to trauma or anatomic abnormalities, qualitative platelet abnormalities

↑ Increased; ↓ Decrease; APTT: Activated partial thromboplastin time; DIC: Disseminated intravascular coagulation; INR: International normalized ratio; N: Normal

present in these cases.¹³ In India and other developing countries such stringent diagnostic criteria may be difficult to follow. Fibrinogen and PIVKA estimation are usually not available. A deranged PT which gets corrected after VK administration should be enough to label the cases as VKDB. The inclusion age for VKDB was extended to 24 weeks.¹³

Early Vitamin K Deficiency Bleeding

E-VKDB has its onset in first 24 hours of life. It is classically described in babies born to mothers who are malnourished or are receiving drugs which interfere with VK activity. Due to transplacental transfer of these drugs, the VK dependent factor levels of the neonate may get reduced. These drugs include anticonvulsants (phenytoin, barbiturates and carbamazepine but not valproate), antitubercular drugs (isoniazid and rifampicin but not pyrazinamide) and VK antagonists (warfarins and phenprocoumons). The incidence of VKDB in babies born to mothers on these drugs have varied between 6 to 12 percent.¹³⁻¹⁵ E-VKDB often presents with serious life-threatening intracranial, intrathoracic, intra-abdominal or gastrointestinal bleeding particularly so if the delivery has been difficult.

Classical Vitamin K Deficiency Bleeding

Classical VKDB as described by Townsend¹³ begins in the first week excluding the first 24 h, usually between days 3 and 5 and in babies with delayed or inadequate feeding. Estimates of the frequency vary from 0.5 to 1.5 percent. Bleeding is usually from the umbilicus, the gastrointestinal tract and skin punctures and may cause significant blood loss. Surgical procedures such as circumcision unmask subclinical cases of VKD.¹³ Intracranial hemorrhage (ICH) is rare but can cause significant morbidity or death.

Late Vitamin K Deficiency Bleeding

Late VKDB begins on or after day 8, most often between weeks 2 and 8 but can occur up to 6 months. According to presence of associated factors, the disease is classified as primary-if no factor other than exclusive breast-feeding is identified and secondary-when other associated factors are present. The associated factors are cystic fibrosis, α -1-antitrypsin deficiency, biliary atresia, hepatitis, chronic warfarin exposure and celiac disease.¹⁶⁻¹⁸ Liver diseases have been associated in 73 to 90 percent cases and the cases are reported with bleeding being the first manifestation. Bleeding manifestations in these cases may be in the form of minor skin bleeds or mucosal, gastrointestinal, umbilical bleeding or bleeding from skin injection sites or on surgical intervention. Intracranial and other life-threatening bleeds are also very common.^{19,20} These serious bleeds at times are preceded by milder bleeds—the so called “warning bleeds” such as umbilical oozing, skin bleeds, etc.

Laboratory work up in VKDB, PT and APTT both are prolonged (diagnostic criteria include only prolongation of PT) and platelet count is normal. The activity of VK dependent factors II, VII, IX and X is decreased.¹³ Fibrinogen levels are normal. PIVKA are present and their presence is useful in diagnosis of cases who might have received VK because PIVKA remain detectable even after VK administration. Rapid correction of PT within 30 to 120 minutes of VK administration of VK is diagnostic of VKDB.

Treatment of VKDB

Replacement of VK is the treatment required. Intravenous or subcutaneous administration of 2 to 5 mg VK is recommended. Intramuscular administration should be avoided as it may result in hematoma formation.

VK-Prophylaxis: In most centers 1 mg of intramuscular VK is given at birth as VK prophylaxis for VKDB. Oral and intramuscular VK (one dose of 1 mg) protect equally well against classical VKDB but intramuscular VK is more effective in preventing late VKDB. It is due to the short half-life of VK because of which levels of VK decrease very rapidly. By 2 weeks VK levels in normal breastfed infants given 1 mg VK1 orally at birth are approximately 0.8 ng/ml, and subsequently fall to unsupplemented levels.¹³ So, repeated doses should be given orally. Oral VK prophylaxis is best provided by weekly oral doses of 1 mg VK or by daily oral doses of 25 to 50 μ g for 3 months.

MANAGEMENT OF A BLEEDING NEONATE

Firstly the cardiorespiratory stability should be checked in the baby with bleeding. In addition to ensuring adequate vitamin K, many coagulation factor abnormalities may be corrected with intravenous administration of 10 to 15 mL/kg fresh frozen plasma.¹ Use of cryoprecipitate may be indicated with factor VIII deficiency (congenital or acquired with DIC) and/ or hypofibrinogenemia. The potential hazards of transfusion of blood products should be kept in mind. The risks may be lessened by the use of heat-inactivated products and with appropriate blood banking procedures. The complications of continued bleeding are potentially more severe. Although no well controlled studies are available, suggestions have been given regarding indications for platelet transfusion.^{4,12} The following guidelines may be considered:

- For premature infants, platelet count of less than $50 \times 10^9/L$ in a stable infant as clinically assessed and platelet counts of less than $100 \times 10^9/L$ in a bleeding infant or if surgery is anticipated; and
- For term infants, platelet count less than $30 \times 10^9/L$ in a stable infant and platelet count less than $50 \times 10^9/L$ if there is bleeding or need for an invasive procedure.

More liberal criteria (e.g. platelets less than $100 \times 10^9/L$) may be used for platelet transfusions when bleeding is severe (e.g. DIC). Other therapy such as the use of IVIG for neonate alloimmune thrombocytopenia may also be helpful.¹²

Hypothermia in Newborns

Avneet Kaur

Temperature control is essential to survival, and studies since 1950s have shown that neonates with hypothermia have poor outcomes. Despite all that is known about heat loss in infants, hypothermia continues to be a significant problem especially in VLBW infants. A newborn baby is physiologically homeothermic and his ability to stay warm may easily be overwhelmed by extremes of environmental temperatures. Neonatal hypothermia often due to lack of attention by health care providers continues to be a very important cause of neonatal deaths.

THERMOREGULATION IN NEWBORN

Fetal temperature is approximately half a degree (centigrade) higher than maternal temperature *in utero*. This temperature relationship (fetus > mother) results from a combination of endogenous heat production by the fetus and the surrounding core temperature of the mother. To dispose of excess endogenous heat, the fetus temperature must be greater than maternal core temperature, creating the necessary temperature gradient to support heat transfer. At birth, heat is lost rapidly secondary to the cold external environment and significant evaporative heat losses. Studies from the 1970s demonstrate that core body temperatures drops 0.1°C per minute which is equivalent to a heat loss of 200 kcal/kg/minute. The body temperature of premature infants drops precipitously after birth because of their disproportionate body mass-to-surface ratio, exposed body posture, decreased amounts of subcutaneous fat, poor vasomotor control, and thin skin with increased permeability. Indeed, despite attempts to reduce heat loss in the delivery room, data collected by the Vermont Oxford Network demonstrate that 27.8 percent of VLBW infants have admission temperatures less than 36°C. Unless someone gives immediate attention to heat loss, the neonate's temperature can drop approximate

4.5°C (8.1°F) during the first minute after birth. Because the infant is dependent on environmental temperature, providing thermal support is a primary nursing objective.

RESPONSE TO COLD

Muscular Activity

During exposure to cold, baby feels uncomfortable, cries and makes some movements of limbs but the effort is not sustained. Shivering does occur but is minimal especially in LBW babies and appears only when the environmental temperature falls below 25°C. Thus muscular activity is not a significant source of heat production.

Metabolic Thermogenesis

Nonshivering thermogenesis, as a result of metabolism of the brown fat, is the most important source of heat production in the newborn. The fetal brown fat is laid down mostly during the third trimester of pregnancy and is located at the nape of the neck, interscapular region, axillae, groin and around kidneys and adrenals. Brown fat is characterized by a rounded nucleus, granular cytoplasm with a large number of mitochondria (with yellow mitochondrial cytochromes) and fat vacuoles. This fat is metabolically very active in view of a large number of mitochondria and increased vascularity.

When the skin of the baby becomes cold, afferents convey the message to the heat regulating center located in the preoptic anterior hypothalamic area near the walls of the third ventricle. Neurogenic efferents, on reaching the brown fat, trigger the local release of noradrenaline so that triglycerides are oxidized to glycerol and fatty acids. The blood level of glycerol rises but fatty acids are locally consumed for the generation of heat. About 30 percent of nonesterified fatty acid are oxidized to generate heat, 60

percent are re-esterified and 10 percent are released in the circulation. The areas of brown fat become warm and heat is distributed to various parts of the body through blood stream. It is obvious that the baby would need extra oxygen and glucose for this metabolic effort in order to keep itself warm. Effective metabolic thermogenesis demands integrity of central nervous system pathways, adequacy of brown fat and availability of glucose and oxygen.

Thermoneutral Environment

The narrow range of environmental temperature at which a given baby can maintain normal body temperature with minimal oxygen consumption (and possibly minimal fuel consumption) is called thermoneutral temperature or zone of thermal comfort. This is the ideal temperature at which the babies should be nursed to achieve optimal somatic and brain growth. The baby is most comfortable and sleeps better when nursed in this temperature. This is also called as the zone of thermal comfort. An isolated measurement of body temperature may fail to indicate whether a baby is being subjected to a thermal stress or not. Even when the environmental temperature deviates beyond the thermoneutral range, the infant tries to maintain his body temperature by increasing oxygen consumption and heat production. A fall in the environmental temperature merely by 2°C below the neutral range, triggers infant's metabolic machinery to generate 25 percent additional heat. The environmental temperature at which the metabolic response becomes necessary is called the critical temperature. In a clinical setting, thermoneutral temperature can also be defined as that as a narrow range of environmental temperature in which a baby can maintain core temperature between 36.7°C and 37.3°C and his mean core and skin temperature does not change more than 0.2°C and 0.3°C per hour respectively when recorded continuously by an electronic thermometer.

Heat Loss (Fig. 1)

Newborn loses heat by:

- Evaporation particularly soon after birth (amniotic fluid from skin surface)
- Conduction (contact with cold objects cloth, tray, etc.)
- Convection (by air currents—cold air replaces warm air around baby—open windows, fans)
- Radiation (to colder solid objects in vicinity-walls).

Hypothermia (Fig. 2)

Hypothermia in a newborn is defined as a core temperature of <36°C. When core temperature is between 36 and 36.5°C it is known as cold stress. The difference in core and peripheral temperature is more than 1.5°C and extremities are cold and pale. Babies in cold stress have poor growth velocity as glucose is wasted for metabolic thermogenesis. Moderate hypothermia is diagnosed as core temperature

ranges between 32 and 35.9°C while a core temperature of <32°C is designated as severe hypothermia.

Risk Factors for Hypothermia

Situations contributing to excessive heat loss: Cold environment, wet or naked baby, cold linen, procedures like surgery. Increased airflow currents coupled with low humidity causes greater convective and evaporative losses.

Poor ability to conserve heat: Preterm and small for date infants have poor thermoregulation due to:

- High surface area and decreased subcutaneous tissue
- Decreased brown fat
- Decreased glycogen stores
- Inability to reduce effective surface area by assuming flexed posture and poor muscle tone.

Poor Metabolic Heat Production

- Central nervous system damage due to anoxia, intracranial hemorrhage and malformations interfere with the integrity of neurogenic pathways for stimulation of brown fat
- Hypoxia
- Hypoglycemia
- Deficiency of brown fat, e.g. preterm and small for dates babies.

Fig. 1: Various mechanisms of heat loss

Fig. 2: Definition of neonatal body temperature variations

Clinical Manifestation and Consequences of Hypothermia (Flow Chart 1)

Numbers of manifestations are seen if thermal environment is below the neutral range of environmental temperature. The baby is uncomfortable, restless, and cries to generate muscular activity. Next the baby may become inactive and sluggish. Skin feels cold to touch and is mottled. Weak cry, poor feeding, bradycardia, shallow respiration, apnea, fall in blood pressure are other manifestations. Weight gain is unsatisfactory due to loss of energy in heat production rather than tissue growth.

The immunological system is depressed with enhanced susceptibility to develop sepsis, sclerema, DIC. Biochemical derangements include hypoglycemia due to increase glucose consumption during thermogenesis. Metabolic acidosis occurs due to anaerobic metabolism. There is rise in serum potassium and BUN levels following tissue catabolism.

Management of Hypothermic Newborn

Hypothermic babies should be rewarmed measures for warming infant includes:

- Ensuring infant is dry. Remove all wet towels.
- Radiant warmer or incubator can be used for rewarming. Set the desired temperature on the radiant warmer or incubator. Set the desired skin temperature on the radiant warmer or incubator and allow the baby to rewarm (set skin temperature at 36.5°C in skin

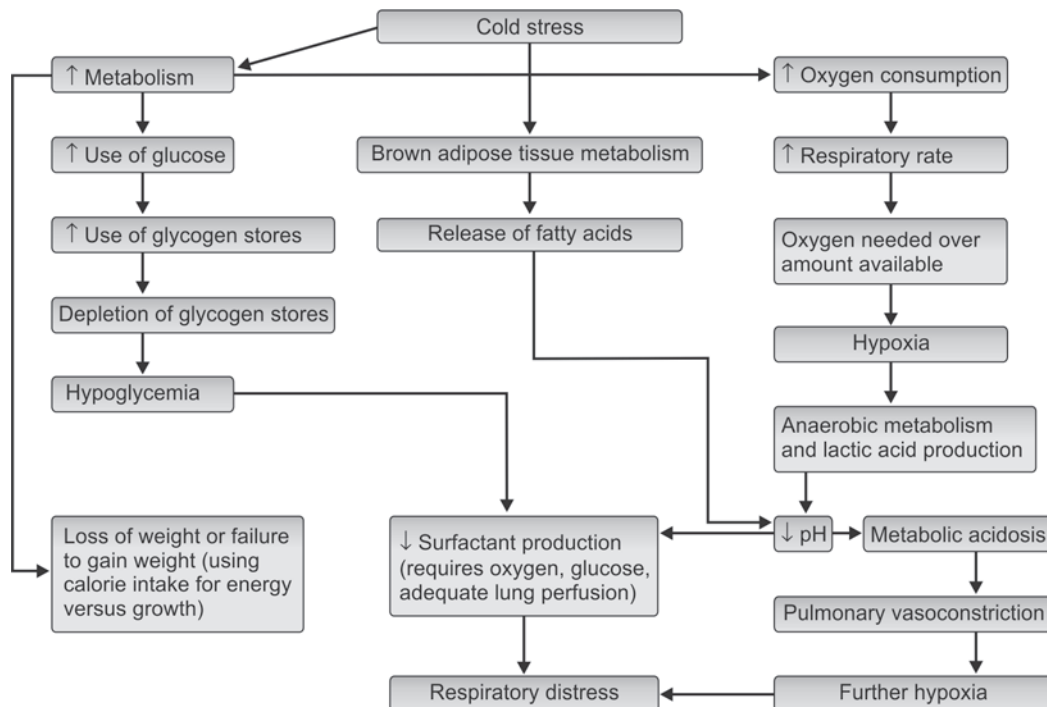

servo mode/or set air temperature at 35 to 36°C in air servo mode).

- Monitor temperature, oxygen saturation with pulse oximeter, CFT and blood sugar.
- In absence of a radiant warmer or incubator, a heating lamp kept at least 50 cm away from infant can be used. Warm blankets, cotton wool, hot water bags may be used under supervision.
- Providing supervised KMC, skin—skin contact is best method to rewarm a baby with hypothermia especially during transport.

Supportive Care

- Prompt detection and management of hypoxia, hypoperfusion and hypoglycemia.
- Dextrose infusion at 6 to 8 mg/kg/min and injection K should be given if not given at time of birth.
- If perfusion is poor give 20 ml/kg of ringer lactate or normal saline over 15 to 20 min. Provide oxygen in case of moderate to severe hypothermia
- Watch for apnea, hypoxia and hypoglycemia during rewarming. Very rapid rewarming can cause apnea. If an infant becomes apneic during rewarming, rate of rewarming should be slowed. Once the temperature reaches 34°C, the rewarming process should be slowed down to avoid overheating. On occasion it may be necessary to halt the warming process completely for a period to allow the infant to adjust to the new conditions, even though infant may still be hypothermic.

Flow chart 1: Physiological consequences of cold stress

Prevention of Hypothermia

Delivery Room

One basic mechanism to prevent heat loss is manipulation of the environmental temperature. Environmental temperature refers to the aggregate influence of the environment on body temperature. Delivery rooms are sometimes kept at a temperature comfortable for the mother and staff with little consideration of the newborn. This results in greater temperature gradients between the infant and the air (increased convective losses) and cool walls (increased radiant losses). Interventions that increase air temperature in delivery area reduce convective and radiant heat loss. Prewarming of surfaces and items coming in contact with the infant will result in reductions in conductive heat losses. Table 1 provides recommended delivery room temperatures on the basis of gestational age.

Heat Loss in Postnatal Ward and During Transport

Ensure that baby is kept warm with appropriate clothing and skin-to-skin contact with mother. Change wet clothing promptly and keep baby dry. Keep windows closed and cover baby adequately. Continue breastfeeding day and night. If a baby needs to be transferred inform NICU at least half an hour before the transfer so that radiant warmer is switched on to maintain thermoneutral environment. The simplest way to transport is by doing kangaroo mother care. If baby is unstable a transport incubator is preferred. If transport incubator is not available, thermocol box or plastic box with holes may be used. If baby is on oxygen ensure that it is adequately warm and humidified. If baby is not on IV fluids, feeding should be continued during transport. If mother is accompanying baby breastfeeding every 1 to 2 hours can be offered and if mother is not accompanying, careful spoon feeding or gavage feeding could be offered.

Kangaroo Mother Care

Kangaroo mother care is a nonconventional method of caring of low birth weight and preterm newborns. The major components of KMC are:

- Skin-to-skin contact. Babies are kept, day and night, between the mother's breasts firmly attached to the chest in an upright position

- Frequent and exclusive or nearly exclusive breastfeeding
- Early discharge from hospital regardless of weight or gestational age. Respiratory, thermal and feeding stabilization are crucial for the success of this intervention. Prolonged skin-to-skin contact between the mother and her preterm/LBW infant, as in KMC, provides effective thermal control and may be associated with a reduced risk of hypothermia.

Temperature Regulation in NICU

Healthy infant over 34 weeks can be adequately nursed fully clothed, in a cot, in a warm centrally heated room. Ambient room temperature should be 28 to 30°C for all babies. Smaller babies and mature, but ill infants, require a more controlled thermal environment. It is important to further reduce heat loss by controlling all 4 methods of heat exchange. To reduce conductive heat loss, it is recommended that any surface in direct contact with the infant be prewarmed. This includes radiant warmers, incubators, in-bed scales, blankets, wraps, clothing, thermal mattresses, and X-ray plates. Reduction in convective heat loss requires a warm environmental temperature without drafts and the need for warm gases for respiratory support. Evaporative heat loss can be controlled by drying the infant using a prewarmed wrap and hat, providing a humidified environment, and using humidified oxygen. Heat shielding mechanisms like polyethylene wraps, plastic heat shields can be tried. Epidermal barrier protections like aquaphor or emollients have also been used. When placing umbilical catheters utilize a clear plastic sterile drape during the procedure to prevent radiant heat transfer. Although radiant heat loss cannot be totally eliminated, radiant warmers along with measures to prevent other types of heat loss may improve outcomes in VLBW infants.

Radiant Warmer

Radiant warmers provide intense source of radiant heat energy. They also reduce the conductive heat losses by providing a warm microenvironment surrounding the baby. The overhead quartz heating element produces heat which is reflected by the parabolic reflector on to the baby on the bassinet. The quantity of heat produced is displayed in the heater output display panel. This system in which the heater output is determined automatically based on skin temperature information is called *servo system* or manually using *manual mode* of operation.

Convection Warmed Incubators

A modern incubator consists of an optically transparent, plastic hood (3 mm thick) covering the infant, with sidewall and hand-access ports. The infant lays on a bed platform, underneath which a tungsten element electronically heats the air. Air is forced over this element by a fan,

Table 1: Recommended stabilization room temperatures (based on PMA and birth weight)

Estimated postmenstrual age, week	Estimated birth weight, g	Delivery/stabilization room temperature
≤ 26	≤ 750	78-80°F
27-28	751-1000	
29-32	1001-1500	≥ 72°F (goals 75°F)

circulating heated air within the hood. Temperature may be controlled thermostatically to regulate either the air or infant skin temperature. Incubators are widely used for the care of low-birth-weight (LBW) and sick newborns. These devices have numerous advantages, in particular they provide a clean, warm environment in which the temperature and humidity may be controlled, and oxygen may be supplied when necessary. Furthermore, incubators allow easy observation of the naked neonate, and his/her isolation. However, infant incubators have also a number of disadvantages that should be carefully considered. In fact, these devices are expensive, have high running costs, and are potentially hazardous to the baby. Additionally, incubators create a barrier between mother and neonate, which delays bonding and makes breast feeding difficult and also makes difficult access for procedures.

Radiant Warmer Over Incubator

Advantages

- Easy accessibility
- Easy to connect the tubes of ventilated baby and do procedures
- Better monitoring especially if the baby has respiratory distress
- Less risk of infection as compared to closed incubator
- Can be used as resuscitation trolley in the labor room.

Disadvantages

- More insensible water losses
- Not uniform heating as compared to closed system
- More risks of episodes of hypothermia.

In a Cochrane review comparing cot nursing versus incubator for preterms, four studies (179 neonates) were included. The researchers followed the infants' body temperature, weight gain and whether or not they were breastfed. In one study, the cot nursed infants had a higher mean body temperature in the first week of life. Another study showed less weight gain for infants in cots when in a heated room for the first week of life. Higher numbers of infants cared for in cots were breastfed when leaving the health care facilities in a study from Ethiopia. Due to the small numbers of trials included and infants studied, and the resulting imprecision in the measures of effect for all

outcomes, the review does not give a clear indication for the role of cot-nursing for preterm infants.

Humidity

In addition to the air temperature, it is important to control humidity. The evaporative heat loss is very high with dry, draughty air and can lower the infant's core temperature below that of the surrounding air. It is easier to prevent hypothermia by reducing transepidermal water losses (TEWL) than by increasing heat production (Fig. 3). The epidermal barrier matures rapidly over the first 2 weeks of life. Nothing is known to accelerate this maturation process. However, we can alter TEWL by altering relative humidity (RH). At 100 percent RH, TEWL is zero because there is no water vapor pressure gradient driving water loss. An RH of 90 percent will result in a fall of the total body water loss of 45 percent for VLBW infants. At 80 percent to 90 percent RH, the decrease of evaporative skin cooling impedes the fall of body temperature with increase in weight, and decreased fatality in VLBW infants. When RH is raised TEWL will be low regardless of the effectiveness of the infant's epidermal barrier. Earlier there were reports of increased risk of infections with high humidity however no proven data is available. Humidity should be commenced in all infants born at <31 weeks gestation. If <27 wk then start humidity with 85 percent. Set humidity 75 to 85 percent for at least the first 14 days then gradually reduce humidity (5% daily) (Table 2).

Double Percent Walled Versus Single to Walled Incubator

The structural characteristics of incubators may also play a role in maintaining an optimal thermal environment for the newborn. Double-walled incubators, which direct warm air between the inner and outer incubator walls, have been shown to reduce radiant heat loss through the reduction of temperature gradients between the infant and its environment. A recent Cochrane review provided evidence that double-wall incubators compared to single wall incubators decrease both heat loss and oxygen consumption in VLBW infants, but was unable to support the proposition that double-wall incubators have a beneficial effect on long-term outcomes including mortality or the duration of hospitalization.

Table 2: Humidity based on gestation age and day of life

Days	1	2	3	4	5	6	7	8	9	10-15
<28 wk	80%	80%	80%	80%	80%	75%	75%	70%	60%	55-40%
	1	2	3	4	5	6	7	8	9	10
28-30 wk	75%	75%	75%	70%	65%	60%	55%	50%	40%	30%

(Humidity should be reduced with respect to gestation and temperature stability)

Fig. 3: Transepidermal water evaporation from the skin of premature neonates of gestations ranging from 25 to 40 weeks, followed longitudinally from birth over the first month of life. Dehydration is most dangerous in the most immature babies less than 28 weeks of gestation in the first week of life before skin keratinization occurs. (From Sedin G, Hammarlund K, Nilsson GE, et al. Measurements of transepidermal water loss in newborn infants. *Clin Perinatol* 1985; 12: 79-99, with permission.)

Weaning from Incubator to Cot

Weaning from isolette to open crib can be accomplished by manually lowering the incubator's ambient temperature. The infant should weigh at least 1500 grams, have five days of consistent weight gain, should be tolerating enteral feedings as well as an ambient temperature of less than or equal to 31°C and be free of medical complications. The infant's abdominal skin temperature should be 36 to 37°C (96.8-98.6°F) in order to wean to open crib.

Polyethylene Wrap in the Delivery Room

Studies have shown that using a plastic wrap made of polyethylene in babies immediately before or after drying can further minimize evaporative and convective heat losses. Radiant heaters are often used as the sole source of thermal care in the delivery room although they cannot achieve a positive energy balance to warm the premature infant immediately after birth. Occlusive wrap has been clearly established through 4 randomized controlled trials, involving 300 infants, and a Cochrane review, as effective in preventing hypothermia ($<36.5^{\circ}\text{C}$) in premature infants younger than 29-week gestation in the delivery room and significantly improving admission temperatures. A 2005 systematic review found that occlusive wrap significantly improved admission temperature and significantly reduced hypothermia. Occlusive wrap permits heat gain by the infant through radiation and reduces the amount of evaporative heat loss. Studies show decreased mortality in

infants who were cared for using plastic wrap and hat. Polyethylene wrap has shown to reduce insensible water loss by 70 percent and improve temperature control. Despite the use of polyethylene wraps, VLBW infants continue to have problems with hypothermia in the first few days of life and polyethylene wraps must be used in combination with other thermoregulatory measures. Polyethylene wrap placed on VLBW infants before drying in the delivery room may produce a microhumidified environment and improve TEWL and temperature control. The poorly developed epidermal barrier in VLBW infants leads to high TEWL, percutaneous absorption, and trauma. High TEWL leads to poor temperature control and difficulty in fluid balance. It can and should be reduced by manipulation of the ambient humidity and by covering the skin. The wrap serves as a shield for the infant and forms a barrier keeping higher ambient air humidity under the wrap. Once an infant is wrapped in the delivery room, it is essential to maintain that wrap. Reports have shown that infants in NICUs may be manipulated by health care providers up to 30 percent of the total day. The thermal microenvironment may be significantly altered by frequent wrap removal. For example, Lyon et al reported that a reduction in skin temperature of more than 1°C can result in thermal stress, which may lead to hypovolemia. Heat loss has been shown to be minimized by the humidified microenvironment for reasons discussed earlier. Relative humidity that builds up in the microenvironment underneath the wrap will drop quickly when the infant is unwrapped, TEWL will increase at the same time, and the infant's body temperature will fall. It may take a while once closed for humidity to increase again. The clear plastic wrap allows the provider to observe and assess the infant. It is essential for health care providers to learn techniques to effectively wrap the infant so that unwrapping is unnecessary even for procedures such as umbilical catheters. Despite advances in technology, 31 to 78 percent of VLBW infants exhibit cold body temperatures after delivery room stabilization, and improvement in care remains a significant challenge to the health care team. In 2005, the American Academy of Pediatrics and the American Heart Association recommended that polyethylene bags in the delivery room be considered for prevention of heat loss in VLBW infants. Optimizing delivery room temperatures combined with the use of occlusive skin wrap may be the best method for decreasing hypothermia in VLBW infants.

Transwarmer Mattresses

There has only been 1 small study evaluating the use of the transwarmer mattress in VLBW infants in the delivery room. Although this trial demonstrated improved admission temperatures in the mattress treated group, the study is too small to make recommendations.

Further studies are needed looking at the addition of transwarmer mattresses with wrap to ensure iatrogenic hyperthermia and burning are avoided. There may be a use for this type of warmer during transport in a cohort of infants who, despite maximal thermoregulatory control, still arrive cold in the NICU.

Hats

Heat exchange between the uncovered head and the environment is very high. Use of stockinet caps has not been shown to improve core body temperatures in VLBW infants and currently there are 2 studies evaluating woolen hats and showing an improvement in temperature in the first 30 minutes of life. A Cochrane review looking at measures to reduce hypothermia concluded that hats had only a minimal effect in reducing heat loss from the head. There have been no studies looking at the effect of hats in VLBW infants. One issue is that currently available hats prevent heat from escaping but do not prevent evaporative heat loss. In infants wrapped in plastic bags, the large surface area of the infant's head remains available for evaporative heat loss. About 50 percent of the total heat loss is through the head. One small study evaluated the use of a polyurethane-lined hat and was able to show a reduction in cranial heat loss between 63 percent and 72 percent. It is clear that the use of stockinet or cotton hats does not provide adequate thermoregulatory support for VLBW infants. The addition of the plastic wrap under the hat may make a significant difference in heat loss and improve thermoregulation in VLBW infants. Development of strategic wrapping techniques by delivery room staff to place the wrap under the hat may decrease thermal losses.

Warm Chain Ten Commandments

Warm chain should be maintained for maintenance of newborn's temperature. The warm chain is set of ten interlinked procedure carried out at birth and during the following hours and days which will minimize the likelihood of hypothermia in all newborns:

- *Warm delivery room:* Maintain delivery room temperature 25°C (28 ± 2)
- *Warm resuscitation:* Use warm equipment and sheets for resuscitation
- *Immediate drying:* Dry baby thoroughly immediately after birth, take care not to ignore head, axilla and groin. Discard the wet sheet used for drying baby and wrap baby in another dry and warm sheet.
- *Skin-to-skin contact between mother and baby:* Keep baby in between mother's breast in skin to skin contact this helps to keep baby warm.
- *Breastfeeding:* Initiate breastfeeding early, preferably within half an hour of birth.
- Bathing and weighing postponed
- Appropriate clothing and bedding

- Mother and baby together (rooming in)
- Warm transportation
- Training and awareness of health care providers.

Hypothermia as Neuroprotection

Neuroprotection with brain-specific therapies has been well studied in the preclinical arena over the past 20 years, with the aim of blocking or dampening the cascade of events triggered by hypoxia and ischemia. Brain hypothermia is a promising therapy for neuroprotection against encephalopathy presumably due to hypoxic-ischemia.

Mechanism of Action of Hypothermia

- Reduces cerebral metabolism, prevents edema
- Decreases energy utilization
- Reduces/suppresses cytotoxic amino acid accumulation and nitric oxide
- Inhibits platelet-activating factor, inflammatory cascade
- Suppresses free radical activity
- Attenuates secondary energy failure
- Inhibits apoptosis (cell death)
- Reduces extent of brain injury.

Various randomized, controlled trials and one large pilot study have been published evaluating hypothermia as neuroprotection for term and near-term infants who have HIE. The multicenter Cool Cap Study involved 243 infants who had moderate or severe encephalopathy and abnormal aEEG amplitudes and were either cooled to a temperature of 34.0 to 35.0°C for 72 hours or treated with temperature maintenance in the normothermia range with conventional care. The primary outcome of the study was death or disability at 18 months. Cooling was provided by selective head cooling and mild systemic cooling. Death or severe disability occurred in 66 percent of infants randomized to conventional care and 55 percent randomized to the cooled group (odds ratio [OR] 0.61, 95 percent confidence interval [CI] 0.34 to 1.09, $P < 0.10$). The effect of head cooling for infants who had the most severe aEEG changes was not protective, but the effect of head cooling for infants who had less severe aEEG changes ($n = 172$) was protective (OR 0.42, 95% CI 0.22 to 0.80, $P < 0.009$). The large randomized, controlled pilot study performed at seven centers of 65 infants involved moderate systemic whole body hypothermia to 33.0°C for 48 hours compared with normothermia maintained at 37.0°C. The safety report of this pilot study documented that infants in the hypothermia group had more significant bradycardia, longer dependence on pressor medications, higher prothrombin times, more seizures, and need for more plasma and platelet transfusions. At 12 months of age, death or severe motor scores were documented in 52 percent of the hypothermia group compared with 84 percent of the normothermia group ($P < 0.02$). In a subgroup analysis, out

born infants were more likely to die than inborn infants (OR 10.7, 95% CI 1.3 to 90.0). The National Institute of Child Health and Human Development (NICHD) Neonatal Research Network trial of whole-body hypothermia for infants who had moderate and severe encephalopathy randomized 102 infants to hypothermia to 33.5°C for 72 hours and 106 control infants to conventional care. The primary outcome was death or moderate/severe disability at 18 months of age. The infants in the hypothermia group had significantly lower heart rates than the infants in the control group throughout the 72-hour intervention period.

There was no significant difference in systolic or diastolic blood pressure between groups. The frequency of adverse events during study intervention was low: one infant in each group had arrhythmia, two infants in the hypothermia group had acidosis, three infants in the hypothermia group and two control group infants had bleeding, and four cooled infants had altered skin integrity. The primary outcome was noted in 44 percent of infants in the hypothermia group compared with 62 percent of infants in the control group, with a risk ratio of 0.72 (0.54 to 0.95). There was a trend for cooling to benefit infants in both moderate and severe encephalopathy groups. The Cool Cap and the NICHD Whole Body Hypothermia Trial used different entry criteria, distinguished primarily by the use of the aEEG in the Cool Cap trial. The mode of cooling used in each trial was different and it is not known if one cooling regimen is superior to the other. The primary outcomes were not defined in a similar manner in the two trials. Although not powered to evaluate moderate or severe encephalopathy separately, decreases in death and moderate/severe disability were seen in the whole body cooling trial in both the moderate and severe encephalopathy groups. The primary outcome of each trial was the combined end point of death or disability; hypothermia therapy did not salvage infants who had severe disabilities and would have died in the absence of the intervention. The rate of disabling cerebral palsy was reduced from 31 percent in the control group to 18 percent in the Cool Cap Study and from 30 percent in the control to 19 percent in the whole-body cooling trial of the NICHD Network.

Meta-analyses of Trials

Three independent systematic reviews have concluded that therapeutic hypothermia significantly reduces both death and disability after perinatal encephalopathy and is safe and that outcomes are homogeneous both within and between trials (Tables 3 and 4).

Gaps in Knowledge

All of the current published trials have evaluated hypothermia as a neuroprotective strategy with the primary

Table 3: Meta-analysis of hypothermia for term infants who have encephalopathy

<i>Outcome</i>	<i>Relative risk (95% confidence interval)</i>
Death or moderate/severe disability	
Shah 2007	0.76 (0.65 to 0.88)
Schulzke 2007	0.78 (0.66 to 0.92)
Jacobs 2007	0.76 (0.65 to 0.89)
Mortality	
Schulzke 2007	0.75 (0.59 to 0.96)
Jacobs 2007	0.74 (0.58 to 0.94)
Moderate/severe disability	
Schulzke 2007	0.72 (0.53 to 0.98)
Jacobs 2007	0.68 (0.51 to 0.92)

Table 4: Stage of HIE and response to therapeutic hypothermia

	<i>Death or disability: cooled</i>	<i>Death or disability: control</i>
Moderate HIE		
Whole body cooled		
NICHD trial	32%	48%
Cool Cap trial	45%	57%
Severe HIE		
Whole body cooled		
NICHD trial	72%	85%
Cool Cap trial	70%	91%

outcome of death or disability at 18 months of age. To assess efficacy in childhood, assessments of school-age outcome are being evaluated in the Cool Cap and NICHD Network Trial. The role of cranial imaging in predicting outcome among infants undergoing hypothermia is being evaluated from magnetic resonance imaging studies obtained in the NICHD trial. The role of initiating hypothermia beyond 6 hours of age in term infants is being examined because evidence suggests that effects of brain injury following hypoxia-ischemia in the preclinical model continues beyond the 6-hour therapeutic window. Hypothermia as neuroprotection for the 34 to 36 weeks' gestation neonate who has encephalopathy also is being investigated. The impact of hypothermia initiated during transport at less than 6 hours of age has not been demonstrated. The optimum depth and duration of cooling for demonstrating greater neuroprotection is unknown. Head cooling versus whole body cooling which is better is not known. Hypothermia in resource poor setting is still being evaluated. The role of pharmacologic agents used in conjunction with hypothermia as neuroprotection for hypoxic-ischemic brain injury is being investigated in preclinical studies. Of note, disability is high with severe HIE in spite of therapeutic hypothermia.

Neonatal Abstinence Syndrome

Arun Soni, Saurabh Singh

INTRODUCTION

A newborn infant born to a mother addicted to opioids is at risk for drug withdrawal. At delivery, the discontinuation of opioids from the maternal circulation can lead to a constellation of withdrawal symptoms known as the neonatal abstinence syndrome (NAS).

The term opioid refers to natural and synthetic substances with morphine-like activity. Opiate refers to a subclass of opioids consisting of alkaloid compounds extracted from opium, including morphine, codeine, heroin, and methadone.

EPIDEMIOLOGY

Data from India is not available. In one study from California, the reported prevalence of maternal opioid drug use at the time of delivery was one percent.¹

Among infants with prenatal exposure to opioids, withdrawal will occur in 42 to 94 percent of infants.²⁻⁷ There appears to be a dose-response relationship because several studies have shown an increased risk of neonatal withdrawal and severity of symptoms as the cumulative maternal doses of opioids increase during the last trimester of pregnancy.^{3,8-11} However, in contrast, one large retrospective report of 330 women treated with methadone found no correlation between maternal methadone dose and rate of NAS.¹²

A recent retrospective study of 232 infants born to opioid dependent mothers identified perinatal risk factors for neonatal withdrawal. The data suggest that timing of delivery, mode of delivery, and last maternal methadone dose are significant risk factors for the development of NAS requiring treatment.¹³

In the United States, heroin and methadone are the most common opioids that infants are exposed to

prenatally. In the general population, heroin is the most commonly abused opioid. Because withdrawal of opioids from the mother is associated with significant fetal distress and demise, medical detoxification is rarely attempted and pregnant women need to be maintained on an opioid. For addicted pregnant women, methadone is the drug of choice because it is easier to administer and manage than other opioids.

CLINICAL MANIFESTATIONS

Newborn infants who withdraw from opioids present with a well-recognized constellation of symptoms known as the neonatal abstinence syndrome.¹⁴ These findings include:

- *Central nervous system:* Tremors, irritability, increased wakefulness, high-pitched cry,¹⁵ hypertonicity and hyperactive reflexes, seizures, yawning, sneezing, and skin excoriation due to excessive rubbing. In addition, they are more likely to have benign neonatal sleep myoclonus compared to infants without NAS.¹⁶ In the absence of other neurological findings, this condition requires no further evaluation or treatment.
- *Gastrointestinal:* Poor feeding, uncoordinated and constant sucking, vomiting or regurgitation, loose or watery stools, dehydration.
- *Autonomic/metabolic signs:* Increased sweating, nasal stuffiness, fever, temperature instability, tachypnea, and mottling of the skin.

Withdrawal from heroin is usually apparent within 48 hours after birth and with methadone 48 to 72 hours after birth. However, withdrawal may be delayed as late as four weeks with both drugs.¹⁴

In addition, infants born to mothers who are substance abusers are at risk for preterm birth and intrauterine growth restriction.¹⁷

Evaluation of *in utero* opioid exposure to premature infants <35 weeks gestation is more complicated because these infants appear to have decreased severity of withdrawal symptoms compared to term infants.³ Possible explanations of the decrease in symptomatology in preterm compared to term infants may be due to developmental immaturity of the preterm central nervous system (e.g. dendritic ramifications, specific opiate receptors, or neurotransmitter function), or reduced total drug exposure during the intrauterine period.

DIAGNOSIS

The diagnosis of prenatal opioid exposure is based upon a history of positive opioid identification in either a maternal or neonatal specimen. If there is a negative or no maternal screening, neonatal screening of meconium or urine samples is indicated in infants with maternal or infant characteristics known to be associated with drug use in pregnancy.¹⁴

Infants who have clinical findings that are suggestive of NAS should be screened.¹⁸

Meconium drug testing is more sensitive than neonatal urine testing in identifying fetal exposure to opioid drug use.² Urine screening of the newborn has a low sensitivity (high false-negative rate) because only infants with recent exposure will have a positive test. The ability to detect *in utero* drug exposure was reported to be similar in umbilical cord tissue compared to meconium samples.¹⁹

DIFFERENTIAL DIAGNOSIS

Other common neonatal problems may have similar features to the neonatal abstinence syndrome (NAS). This includes infantile colic, infections (such as sepsis), and metabolic abnormalities (such as hypocalcemia, hypoglycemia, and hypothermia). Clinical signs should not be attributed solely to withdrawal without appropriate assessment and diagnostic tests (such as screening of opioid exposure, complete blood count, blood cultures, and electrolytes) to differentiate these diseases from NAS.

MANAGEMENT

The goal in an infant who is not irritable, has no vomiting or diarrhea, can feed well and sleep between feedings, and yet is not heavily sedated. Neither give naloxone to these infants nor to one whose mother was on methadone it may precipitate immediate withdrawal or seizures.

Scoring Systems

Several abstinence scoring methods (e.g. Lipsitz tool, neonatal abstinence scoring system, and the neonatal withdrawal inventory) have been developed based upon the clinical manifestations of NAS.²⁰⁻²² These tools measure the severity of neonatal withdrawal and can be used to guide

management. In each clinical setting that cares for infants with NAS, an abstinence scoring system should be adopted as it provides a semiobjective and standardized assessment of the patient's withdrawal symptoms. Scoring systems are used to initiate, adjust, and wean pharmacologic therapy.

The neonatal abstinence Finnegan scoring system is the most widely used of these methods and assesses 31 specific clinical items.²¹ Pharmacologic therapy is generally started with three or more scores above eight. Each institution decides upon the number of consecutive scores below a threshold value for initiation of weaning. It is also mandatory to observe the infant for 2 to 3 days before discharge.

Supportive care: The initial treatment of NAS should be supportive, because pharmacologic therapy may not always be needed and will prolong hospitalization. Supportive care includes:¹⁴

- Decreased sensory stimulation (e.g. quiet room with low lighting and swaddling of the infant)
- Administer small frequent feedings
- Administer calorically dense formula (24 cal/oz) or fortified breast milk (for mothers on methadone) to supply additional calories. Estimated caloric intake for adequate growth ranges from 150 to 250 cal/kg per day because of the infant's increased metabolic needs.¹⁴

Breastfeeding: Breastfeeding by mothers who continue to abuse heroin is not recommended because heroin is excreted into breast milk resulting in adverse effects on the infants.²³ Breastfeeding by mothers who continue to use methadone appears to be safe.²³ Monitor weight and readjust dietary intake to ensure appropriate growth. Poor weight gain in the face of adequate caloric intake may reflect the need to introduce pharmacologic intervention as well as increase the pharmacologic doses being utilized.

- Monitor temperature stability, sleeping patterns, and gastrointestinal symptoms (e.g. diarrhea and vomiting). The presence and persistence of these findings may indicate the need for pharmacologic therapy.

Skin care: The best approach to prevent skin excoriation due to excessive rubbing is to swaddle the infant, thereby reducing trauma to the skin.

In those patients with skin excoriation, routine skin care includes keeping the area clean, dry, and open to the air. Topical barrier creams used to treat diaper dermatitis may also be applied to affected areas to protect the skin and prevent further damage.

Pharmacologic therapy: Pharmacologic intervention is aimed at the short-term improvement of clinical symptomatology. Long-term benefits from treatment, in the symptomatic infant, still remain unproven.

Indications for pharmacologic therapy: Infants with confirmed prenatal drug exposure who are asymptomatic or respond to supportive care do not require pharmacologic treatment.

Indications for drug therapy include:¹⁴

- Seizures
- Poor feeding with failure to gain weight, especially when adequate calories are being ingested
- Inability to sleep
- Fever unrelated to another source
- Significant diarrhea and/or vomiting resulting in weight loss or hypovolemia.

If an abstinence scoring method is utilized, pharmacologic treatment is initiated when the assessment of the infant's symptoms exceeds a predetermined score.

Opioid therapy: If pharmacologic treatment is necessary, opioid therapy is recommended. In a meta-analysis of randomized or quasi-randomized controlled studies, opioid therapy (morphine, paregoric, or methadone) was compared to supportive care alone or sedative treatment (Phenobarbital or diazepam).²⁴ Results of the same were as follows:

- In one study, opioid therapy compared to supportive care alone reduced the time to regain birth weight and duration of supportive care. Opioid therapy increased the duration of hospital stay. Infants included in this study had three consecutive scores on the Neonatal Abstinence Scoring System that exceeded the predetermined score indicated for treatment.
- In an analysis of four studies, there was no difference in treatment failure rate in infants treated with opioid compared to those who received Phenobarbital.²⁶⁻²⁸ In three of the four studies, inclusion criteria were based upon the infant exceeding a predetermined score on a NAS scoring system indicating requirement for treatment.^{25,26,29} In a subset analysis of one of the studies, opioid compared to phenobarbital therapy reduced treatment failure in infants with only prenatal opioid exposure.²⁹ In one of these studies, opioid therapy resulted in a shorter duration of therapy (8 versus 12 days).²⁶ There was no difference in the duration of treatment or hospital stay in two of the other studies.^{25,29}
- One study reported a small reduction in the incidence of seizures with opioid therapy compared to phenobarbital.²⁷
- One study reported a significant reduction in treatment days and nursery admissions in infants who received morphine.²⁵
- In an analysis of two studies, there was a reduction in treatment failure in patients who received opioid therapy compared to diazepam (RR 0.36, 95% CI 0.18 to 0.69).

A second meta-analysis compared sedative therapy (phenobarbital, chlorpromazine, and diazepam) to one another or to supportive therapy alone.^{30,31} Results are as follows:

- Phenobarbital compared to supportive care alone does not reduce treatment failure or the time required

to regain birth weight but reduced the duration of supportive care.

- In two studies, phenobarbital compared to diazepam reduced treatment failure.
- There were insufficient data on the use of chlorpromazine or clonidine to be able to recommend either drug in the treatment of infants with NAS.

These results suggest that opioid therapy is better at reducing the symptoms of withdrawal compared to phenobarbital therapy or supportive care alone in infants with significant withdrawal symptoms. However, caution should be exercised, as these studies were limited because many of the infants were exposed to more than one drug of abuse and the long-term effects of opioid therapy are unknown. Despite these concerns, opioid therapy should be used in infants who, despite supportive care, continue to have significant withdrawal symptoms. If a sedative agent is required then Phenobarbital is the preferred medication. Chlorpromazine or clonidine should only be used in the context of a clinical trial because there are insufficient data demonstrating that they are effective in the treatment of NAS.³¹

There are several different forms of opioid therapy, which include the following:¹⁴

- Neonatal morphine solution (NMS): Morphine sulphate is diluted in a concentration of 0.4 mg/ml in distilled water. Dosing scheme is as under

Score	Neonatal morphine solution
8-10	0.8 ml/kg/d divided q 4 hrly
11-13	1.2 ml/kg/d divided q 4 hrly
14-16	1.6 ml/kg/d divided q 4 hrly
17 or greater	2.0 ml/kg/d divided q 4 hrly; increase by 0.4 ml increments until controlled

Once an adequate dose has been found, and infant scores have been <8 for 72 hours, wean by 10 percent of total dose daily. If weaning results in scores >8, restart the last effective dose. Discontinue NMS when the daily dose is <0.3 ml/kg/d. If the scores are low, make sure that the infant is not over sedated.

- Tincture of opium is also referred to as deodorized opium tincture and DTO. The preparation that is used to treat NAS is a 25-fold dilution and contains the same concentration of morphine equivalent as paregoric.
- Paregoric contains anhydrous morphine (0.4 mg/ml) and is also referred to as camphorated tincture of opium. The use of this therapy has decreased because of its additional ingredients. These include antispasmodics (noscapine and paverine), ethanol (high concentration of 45 percent), and the additive benzoic acid (which may compete with bilirubin binding sites).

- Morphine, both parental and oral preparations are available for use in infants with NAS.
- Methadone.

A survey of academic neonatology centers in the United States reported a wide variation in the treatment of infants with NAS pharmacologic treatment.³² The majority of these sites initially used an opioid, most commonly tincture of opium, or morphine sulfate solution or methadone.³² Paregoric and methadone are the opioids most commonly used to treat NAS.³³

If the infant has been exposed to multiple drugs in utero including opioids, opioid therapy should be used if the infant has symptoms of withdrawal.¹⁴

Adjunct therapy: The use of adjunct therapy has been suggested in infants with severe NAS or in those who have been exposed to multiple drugs.

- *Phenobarbital:* Phenobarbital has been added to opioid therapy in infants with severe NAS and in infants exposed to multiple drugs. In one study, the combined use of opioid and phenobarbital therapy compared to opioid therapy alone reduced the length of hospital stay and duration of symptoms.³⁴
- *Clonidine:* Clonidine is used in older children and adults for opioid withdrawal. In a clinical trial of 80 neonates with intrauterine exposure to methadone or heroin, the addition of oral clonidine (1 µg/kg every four hours) versus placebo to standard opioid therapy decreased the duration of pharmacologic therapy (11 versus 15 days).³⁴ Higher doses of opioid therapy were needed in the placebo group. There were no significant short-term complications (e.g. hypertension, hypotension, bradycardia, or oxygen desaturations) in either group. There were three deaths in the clonidine group (myocarditis, sudden infant death syndrome, and homicide). Although, the authors state the deaths were not attributable to combined therapy with clonidine, further trials are needed to demonstrate the efficacy and safety of this therapeutic regimen.

Naloxone: Naloxone may precipitate rapid withdrawal symptoms,³¹ and therefore should be used with caution in the infant exposed prenatally to opioids. In the delivery room, the use of a small dose of naloxone has been suggested for apneic infants who have been exposed to opioids in utero.⁷

However, in most infants whose mothers received opioids during labor, naloxone is not required. This was illustrated in a prospective study that determined the frequency of naloxone administration after the introduction of resuscitation guidelines for neonatal naloxone administration in the delivery room.³⁵ Of the 1000 total births, 434 mothers (43%) received an opioid during labor but only 1 infant received naloxone after delivery. Thirty-six

infants of mothers who received opioids developed respiratory symptoms. In one case, respiratory symptoms may have been due to maternal opioid administration. This infant did not receive naloxone. In the remaining 35 cases, opioid exposure was ruled out as a cause of neonatal respiratory distress.

If naloxone is used, the clinician needs to be aware of the potential risk of rapid withdrawal and be prepared to treat the infant if they become symptomatic.¹⁴

New 2010 NRP guidelines does not recommend routine administration of Naloxone:

Opioid therapy is begun in patients with symptoms that exceed a predetermined level on an abstinence scoring system despite supportive care. The choice of opioid therapy is physician dependent. The dose of opioid therapy is determined by the response of the patient. If the patient remains symptomatic, an increase in drug dose is indicated. Once the patient responds to therapy and a decrease in withdrawal symptoms and weight gain is established, medication can be weaned. Understanding that there are increased metabolic demands of the patient who is withdrawing becomes an important parameter to follow while making decisions in weaning the opioid. The rate of wean is dependent on the patient's clinical status. Use of abstinence syndrome scoring method facilitates this process.

Long-term outcome: It has been difficult to ascertain the long-term effects of prenatal opioid exposure on the developmental outcome of affected children because of confounding variables. These include prenatal factors, such as other drug exposures, prematurity, and low birth weight, and postnatal factors, such as care provider's socioeconomic and educational level.

There have been reports of developmental and behavioral problems in both prenatal methadone and heroin exposed children. However, these studies have had small numbers of patients and confounding risk factors making it difficult to determine the primary contribution of prenatal drug exposure to abnormal outcome.^{36,37}

In contrast, other studies have reported normal outcome as evaluated by the Bayley scales of infant development at six months and one year of age.^{38,39} Another report of in utero opioid exposed infants compared to patients without *in utero* exposure, which controlled for socioeconomic status and birth weight, reported that the amount of prenatal care and the postnatal home factors were more predictive of the infant's developmental performance at two years of age than prenatal drug exposure.⁴⁰

Further large studies controlled for confounding medical and socioeconomic factors are required to determine whether *in utero* opioid exposure has an independent adverse effect on development.

Table 1: Neonatal abstinence score

[illegible]

SUMMARY

1. A newborn infant born to a mother addicted to opioids is at risk for drug withdrawal. These infants present with a constellation of withdrawal symptoms known as the neonatal abstinence syndrome (NAS).
2. Heroin and methadone are the most common opioids that infants are exposed to *in utero*. Withdrawal from heroin is usually apparent within 48 hours after birth and with methadone from 48 to 72 hours after birth. However, withdrawal may be delayed as late as four weeks with either drug.
3. The diagnosis of *in utero* opioid exposure is based upon a positive identification of an opioid in either a maternal or neonatal specimen. Neonatal screening of meconium or urine samples is indicated if maternal or infant characteristics known to be associated with drug use in pregnancy are present and/or if the infant exhibits symptoms suggestive of NAS.
4. Other common neonatal problems including colic, sepsis, and hypoglycemia, have similar features to the neonatal abstinence syndrome (NAS). Careful clinical assessment and diagnostic tests (e.g. neonatal screen for NAS, complete blood count and blood cultures for sepsis, or serum blood glucose level for hypoglycemia) help differentiate NAS from these disorders.
5. It is unclear whether there are any long-term adverse effects on neurodevelopmental outcome in children who were exposed to prenatal opioids.

Treatment—Management of infants with NAS includes:

1. Evaluation of the severity of NAS and response to treatment. We suggest the use of an abstinence scoring method to measure the severity of neonatal withdrawal and guide management.
2. *Supportive care:* Initial treatment of NAS is supportive, because pharmacologic therapy may not be needed and will prolong hospitalization. Supportive care includes decreasing sensory stimulation, providing adequate nutrition for the infant's increased metabolic needs, and assessing the need for pharmacologic therapy (e.g. monitoring temperature stability, sleeping patterns, and gastrointestinal function).
3. *Pharmacologic therapy:* Pharmacologic therapy is indicated for infants who have seizures, weight loss or failure to gain adequate weight, inability to sleep, or fever. If an abstinence scoring method is utilized (Table 1), pharmacologic therapy is initiated when the infant exceeds a predetermined symptomatic score.
4. If pharmacologic treatment is necessary, the initial drug of choice should be an opioid. There are no controlled studies comparing the different forms of opioid therapy including tincture of opium, paregoric, morphine, and methadone. The choice of opioid agent is physician dependent.

Evaluation of the Hypotonic Neonate

Nirupama Laroia

INTRODUCTION

Hypotonia, which manifests as a “floppy infant” is a difficult neurologic problem in the newborn. It is nonspecific and the differential diagnosis includes sepsis, other acute illnesses, systemic disorder such as congestive cardiac failure, central or peripheral neurologic disease, myopathy, metabolic disorders and many genetic disorders. A physician must not only determine tone and strength, but also whether there is motor or psychomotor delay. The process must then be localized to the nervous system. It is useful to divide localization to 2 large groups; the supraspinal conditions that include the brain, brainstem, and the cervical spinal junction that constitute the central nervous system. The other large group of disorders is those affecting the motor unit including the anterior horn cell, peripheral nerve, neuromuscular junction and muscle. A systematic approach to a newborn with hypotonia is discussed in this chapter.

CLINICAL ASPECTS

The first step in evaluation of a hypotonic infant is to obtain a family and past medical history (prenatal, perinatal and neonatal assessment). The prenatal history should include information on fetal movement *in utero*, fetal presentation, and the amount of amniotic fluid present. The obstetric history occasionally may identify both a cause and timing of onset. Maternal exposure to toxins or infection suggests a central cause. It is important to establish an approximate timing of onset of hypotonia. Was it present from birth, did it develop over days? Were fetal movements present throughout pregnancy or did they diminish. Presence of joint contractures at birth (arthrogryposis) especially those affecting ankles and wrists, suggest chronic *in utero* hypotonia. Congenital dislocation of the hip may be seen. Bell-shaped chest and pulmonary

hypoplasia is typically seen when reduced in-utero respiratory effort occurs. Low apgar scores may suggest floppiness from birth and a hypotonic infant should be considered septic until proven otherwise. A full term infant who develops floppiness 12 to 24 hours or so after birth may have a metabolic disorder.

EXAMINATION OF THE HYPOTONIC INFANT

Physical examination will assist in identifying specific constellation of features of recognizable chromosomal or genetic abnormalities such as trisomy 21, Prader-Willi, Smith-Lemli-Opitz, Angelman, and many deletion syndromes. The list of possibilities is extensive and will often require consultation with a geneticist for accurate diagnosis. A discussion of genetic disorders is beyond the scope of this chapter.

Clinical evaluation includes a detailed neurologic assessment including tone, strength, and reflexes. Neurologic examination should include head shape, size, and the size and fullness of the anterior fontanelle. Fundoscopy has limited value. There is paucity of movement while awake and the infant assumes a ‘frog leg’ posture while supine. Truncal tone should be assessed by ventral and horizontal suspension. In ventral suspension, the baby is held upright under the arms; hypotonic infants tend to slide through the examiners hands. In horizontal suspension, the infant is held prone with the examiners hands supporting the infant’s chest and upper abdomen. Infants with hypotonia drape themselves over the examiners hand forming an inverted U, whereas those with normal tone can hold their back straight, their head and legs even with their body. Head control can also be evaluated by pulling the supine newborn up by the arms. The normal term infant should be able to hold the head even with the trunk as they are pulled up. The ‘scarf sign’ is another useful indicator of tone. One arm is pulled across the chest

C

Figs 1A to D: Demonstration of hypotonia; (A) Pull to sit; (B) Scarf sign; (C) Shoulder suspension; (D) Ventral suspension

to the opposite shoulder and the position of the shoulder is observed. The elbow does not cross the midline in normal infants (Figs. 1A to D).

It is important to distinguish weakness from hypotonia. Hypotonia is the impaired ability to sustain postural control and movement against gravity. Thus careful observation of posture in a neonate at various stages of arousal is a sensitive way to assess for hypotonia. In the neonate assessment of gestational age is very important in evaluation of tone. The premature infant demonstrates a

normally lower tone than a full term infant. Weakness is the reduction in maximal power that can be generated. This requires the patient's cooperation and is therefore not possible to test in the newborn. Weak infants always have hypotonia, but hypotonia can exist without weakness.

LOCALIZATION OF HYPOTONIA

Because dysfunction at any level of the nervous system can cause hypotonia, the differential diagnosis is extensive. Central causes are more common than those affecting peripheral nervous system. Hypotonia must first be categorized to central or peripheral origin (Table 1). An alert hypotonic infant that responds appropriately to surroundings, and shows normal sleep wake cycling is more likely to have peripheral nervous system disorder or spinal cord disease. Central causes (Table 2) of hypotonia are often associated with depressed level of consciousness, predominantly axial weakness, and normal strength with hypotonia. A newborn with cortical brain dysfunction is also likely to have early seizures, abnormal eye movements, apnea, or irregular breathing patterns. Peripheral causes (Table 3) are associated with profound weakness in addition to hypotonia and hyporeflexia. Affected infants show an alert, inquisitive face but profound distal weakness. Conversely, an infant who does not track visually, appear lethargic are more likely to have cerebral disorders. Presence of dysmorphic features of face, scalp and malformations of other organs are also suggestive of cerebral involvement.

Table 1: Differentiation of central and peripheral hypotonia

	<i>Central</i>	<i>Peripheral</i>
Mental state	Depressed	Normal
Oculocephalic reflex	Normal or abnormal	Normal or abnormal
Dysmorphic features	May be present	Absent
External anomalies	May be present	Absent
Deep tendon reflexes	Decreased acutely, increased late	Depressed or absent
Cry	High pitched	Weak

Table 2: Causes of central hypotonia in the newborn

Hypotonia present at birth

- Brain and spinal cord injury or trauma: Hypoxic-ischemic encephalopathy, intracranial hemorrhage
- Genetic and chromosomal disorders: Down syndrome, Prader-Willi syndrome
- Cerebral dysgenesis, and other structural abnormalities
- Peroxisomal disorders: Zellweger syndrome, neonatal adrenoleukodystrophy
- Other rare metabolic, genetic disorders
- Benign congenital hypotonia

Hypotonia developing after birth

- Sepsis, including meningitis and encephalitis
- Metabolic derangements or disorders
- Endocrine: Hypothyroidism
- Drug intoxication

Table 3: Peripheral causes of hypotonia*Anterior horn cell (lower motor neuron)*

- Spinal muscular atrophy type I (Werdnig-Hoffman disease)
- Glycogen storage disease type II (Pompe's disease)
- Neonatal poliomyelitis

Level of peripheral nerve

- Demyelinating neuropathies: Hereditary or chronic inflammatory
- Lysosomal (Krabbe's disease)
- Mitochondrial

Level of neuromuscular junction

- *Myasthenia*: Neonatal transient or congenital myasthenia syndrome
- *Toxic-metabolic*: Hypermagnesemia, aminoglycosides
- Infant botulism

Level of muscle

- *Muscular dystrophy*: Congenital myotonic, congenital muscular dystrophy
- *Metabolic myopathies*: Mitochondrial, glycogen disorder, lipid disorders
- *Congenital myopathies*: Nemaline rod, myotubular, others

CENTRAL HYPOTONIA**Systemic Disease**

The most frequent examples of hypotonia from central causes include systemic disorders like congenital cardiac failure, or sepsis. These infants spend all their energy breathing and do not move much. Septic infants also have hypotonia that can be quite severe. These infants have other systemic signs that help the clinician separate systemic disease from neurologic disease.

Infants with hypoxic ischemic encephalopathy may present with altered consciousness initially, and then become hypotonic before becoming hypertonic, as they get older. Infants with metabolic disease may present with hypotonia that may be indistinguishable from sepsis, and the diagnosis may not be clear until the results of the metabolic screen are available.

Nonsyndromic Central Hypotonia

These infants do not have recognizable dysmorphic features, but have abnormalities of the central nervous system and can be categorized based on neuroimaging (MRI) findings.

Cerebral Dysgenesis

Infants may have minor anomalies of the brain, most of which are not in the category of namable cerebral malformations but represent subtle anomalies of brain formation. These infants have a grossly normal brain on neuroimaging. Over time, these children may not be normal but tone may improve with maturation. Subsequent imaging may show delayed or normal myelination.

Benign Congenital Hypotonia

The term 'benign congenital hypotonia' has been used to describe infants who are hypotonic at birth but without a specific underlying diagnosis at birth, and whose tone normalizes during early childhood. The term likely encompasses many different pathologies and affected infants may have other features of cerebral dysfunction (e.g. learning difficulties). Ongoing effort should be directed to establishment of a specific diagnosis.

PERIPHERAL HYPOTONIA

While disorders of the central nervous system may be the most common cause of hypotonia in the newborn, disorders of the peripheral nervous system or the motor unit make up an important group of diagnosis. Early identification is necessary for genetic diagnosis and counseling.

The diagnostic workup is based on an understanding of the anatomy of the motor unit (Fig. 2). A motor unit consists of an alpha motor neuron in the anterior horn of the spinal cord, its single axon, which runs distally in the peripheral nerve, its many neuromuscular junctions, and all the peripheral fibers with which that neuron makes connections. Therefore, the number of motor units in an individual equals the number of motor neurons. The size of a single motor unit is equal to the number of muscle fibers innervated by that single neuron. The number and size of motor units can be determined by both an EMG and muscle biopsy, often essential in arriving at a diagnosis.

Many disorders of the peripheral nervous system can be localized to the various components of the motor unit. The process of evaluating a hypotonic infant is therefore a logical attempt to localize the lesion to the motor unit and consider a differential diagnosis. The common disorders

Fig. 2: Motor unit sketch

that present at birth include spinal muscular atrophy (SMA), congenital myotonic dystrophy (MD) and transient myasthenia gravis (MG).

Spinal Muscular Atrophy

Spinal muscular atrophy (SMA) is a recessive genetic disorder of the motor neuron that may present at any age, although the majority of patients develop symptoms within the first 6 months of age. The most typical symptoms of the most severe form, SMA type I (Werdnig Hoffman's disease) are hypotonia and weakness presenting as poor head control. Feeding difficulties are less common initially as bulbar weakness is rare in this disorder. Mothers may have a history of decreased fetal movement.

Clinical observation will show that the infant has minimal spontaneous activity, and minimal antigravity activity except in the distal muscles (fingers and toes). The infant is typically very alert, and is able to fix and follow with normal eye movements. Atrophy of face muscles may not be obvious initially in the newborn because of subcutaneous fat. The deep tendon reflexes (DTR) are depressed or absent, while sensation is normal. Tongue fasciculation is a classic feature of motor neuron disease but may not always be obvious in the newborn period.

Diagnosis during lifetime depends on blood chemistry, EMG, and muscle biopsy. Muscle enzymes may be normal or slightly elevated (1.5 to 2 times normal). The EMG is helpful if abnormal. Nerve conduction velocity must be normal for the diagnosis of SMA to be made. Muscle biopsy will show a pattern of innervation denervation. A pattern of marked atrophy of muscle fibers associated with hypertrophic type I fibers is pathognomic of SMA.

The prognosis for SMA patients is variable. With infantile onset (onset <6 months), there is 50 percent mortality by 2 years of age. There is no treatment for the progressive weakness. Supportive respiratory care and

physical therapy is important. Death is usually a complication of respiratory failure. It is important to present as much information to the family as possible, so that they can make an informed decision regarding long-term care for their child. The child has normal intelligence.

Spinal muscular atrophy (SMA) is an autosomal recessive disorder; the gene has been localized to chromosome 5q 11 to 13. In families with more than one affected child, linkage analysis may be possible for prenatal diagnosis. Each child of the same parents has 1 in 4 chance of having the disease. Severity of disease is not necessarily consistent.

Disorders of the Neuromuscular Junction

Affected infants have hypotonia, cranial nerve dysfunction (ptosis, bulbar dysfunction, weak cry), areflexia, and normal sensory function.

Transient neonatal myasthenia gravis occurs in about 12 percent of mothers with myasthenia gravis. It is not related to severity, or duration of maternal illness or to maternal antibody levels. Affected infants present with hypotonia, ptosis, feeding difficulties that resolve over weeks or months. The diagnosis is confirmed by an intramuscular or subcutaneous test dose of edrophonium or neostigmine. Neostigmine is preferred to edrophonium as with the former a response is expected within 15 to 30 minutes and lasts for 1 to 3 hours. Ongoing treatment is supportive care and pyridostigmine.

Impaired presynaptic release of acetylcholine by toxins (hypermagnesemia following maternal treatment of pre-eclampsia with magnesium sulfate, or treatment of neonate with aminoglycosides) may result in a hypotonic neonate, but slowly improves over time (hypermagnesemia). Since this hypotonia may be confused with sepsis, further antibiotics may exacerbate it.

Infant botulism results from presynaptic neuromuscular blockade by the toxin released by *Clostridium botulinum*, which may be present in the gastrointestinal tract of the neonate. The disorder has been described in exclusively breast fed infants. The organism originates from the soil, agricultural products, and honey. In addition to hypotonia, there may be feeding difficulties, abnormal pupillary responses and respiratory failure. The diagnosis is confirmed by positive stool culture, or isolation of toxin from stool. Supportive management may be necessary for months until recovery. There is no proven benefit from antibiotics or antitoxin.

Congenital Myotonic Dystrophy

Congenital myotonic dystrophy (MD) occurs in infants born to mothers with MD. Affected infants are extremely hypotonic, with severe facial diplegia and feeding difficulties evident at birth. Respiratory failure and aspiration are frequent complications, often leading to early death.

Infants are often hypotonic at birth, and may present with joint contractures and dislocated hips, suggesting long standing hypokinesia. Examination of the mother often reveals previously unsuspected MD. While normal mental development is possible, intellectual disabilities are common. Individualized support for the infant and family is desirable.

The diagnosis is dependent on physician's ability to diagnose MD in the mother. There may be other affected relatives with early cataracts, diabetes or mild mental retardation. Adults with MD often consider themselves asymptomatic.

The course of MD in the neonate appears to be biphasic. The ventilator dependent infant may begin to have sufficient spontaneous respiration by week 1 to 3. The risk of aspiration decreases after the neonatal period. Although milestones are initially delayed, the child may begin to meet them after 2 to 3 years of age. Joint deformities and club foot are common. The characteristic facial appearance and clinical myotonia become apparent by school age.

The genetic abnormality is a triplet (CTG) repeat in the noncoding region of the DMPK gene. This autosomal dominant gene not only has variable penetrance, but also penetrates to a greater extent with each generation. CTG repeat a length exceeding 34 repeats is abnormal. Molecular genetic testing detects mutations in nearly 100 percent affected individuals and is clinically available. The disease affects both sexes but the mother is usually the affected parent.

Muscular Dystrophy

Genetically determined myopathies are characterized by progressive weakness. The investigation of these disorders is rapidly evolving with the discovery of specific gene mutations. Muscle biopsy may be nonspecific.

Congenital Myopathies with Distinct Histology

Many myopathies are classified according to their histopathology appearance on muscle biopsy. Most present with hypotonia and mild weakness, with the exception of nemaline myopathy and X-linked myotubular myopathy which have severe neonatal presentation with respiratory failure. All congenital myopathies are genetic disorders and inheritance pattern and gene diagnosis are available for many of them.

Metabolic Myopathies

Mitochondrial cytopathies (cytochrome oxidase deficiency, carnitine deficiency, glycogen and lipid disorders) may present in the neonatal period. Diagnosis depends on enzyme assays and muscle biopsy results.

LABORATORY EVALUATION OF THE HYPOTONIC NEWBORN

The laboratory evaluation should help rule out systemic disorders. Routine studies include serum electrolytes, glucose, calcium, magnesium, creatinine and complete blood count. Urine drug screen for maternal drug use, and blood culture and spinal tap should be considered to rule out infection. Serum ammonia and liver function tests may reveal a urea cycle defect. Imaging of the brain is indicated in infants suspected of having central hypotonia. Magnetic resonance imaging (MRI) is superior to computed tomography (CT) scan or ultrasound for revealing anatomic detail of the brain and can delineate structural abnormalities, neuronal migration defects, basal ganglia (mitochondrial disorders) or brain stem defects. Some infants may not be stable enough for an MRI, when CT or ultrasound may be considered.

Karyotype may be indicated when dysmorphic features are present. Hepatosplenomegaly and calcifications in the brain may suggest TORCH infections and urine or saliva culture for CMV may be indicated. If the infant is acidotic, an arterial lactate should be obtained with urine organic and amino acids. Very long chain fatty acids would evaluate a defect in peroxisomal metabolism, such as Zellweger's disease.

With peripheral hypotonia a battery of laboratory investigations (e.g. serum creatine kinase CK, cerebrospinal fluid CSF analysis, nerve conduction studies and electromyography, neostigmine or edrophonium test, and muscle or sural nerve biopsy) may be performed to determine the precise level of the pathological process affecting the motor unit. Great advances in recent years have been made in molecular genetic testing, which in many instances have obviated more invasive investigations. Specific DNA testing must be performed when available.

Specific aspects of these investigations relevant to newborns require clarification to avoid pitfalls in the interpretation of results. Thus, elevated levels of serum concentrations of CK generally imply skeletal or cardiac muscle necrosis, as may occur in rapidly progressive muscular dystrophies and metabolic myopathies. The blood for CK measurement should be obtained before performing the electromyography or muscle biopsy, as these procedures may cause false elevation of CK levels. The CK and isoenzyme levels may be increased 10-fold for up to 1 week following normal vaginal delivery (presumably due to muscle trauma). The CK may be even higher in the context of acidosis (e.g. severely asphyxiated newborns). Other biochemical investigations (e.g. serum lactate and carnitine levels) may be required in specific circumstances. Because of the uncertainty of the normal range for CK values in the newborn, a normal value does not rule out muscular dystrophy before 6 weeks of age.

A chest radiograph may demonstrate a bell shaped chest and enlarged cardiac silhouette signifying cardiomyopathy or thin ribs, presumably related to diminished fetal respiratory movements. The latter observation is a useful clue to antenatal onset of neuromuscular disease. Markedly increased protein concentration in CSF may indicate peripheral neuropathy or specific degenerative conditions (e.g. Krabbe's disease). Nerve conduction studies are consistent and reliable after 32 weeks of gestation. Nerve conduction velocities, which are slower in normal newborns than in older individuals, may be very slow or unrecordable in the context of congenital peripheral neuropathies. The technical performance and interpretation of the electromyogram (EMG) may be problematic in the newborn. For example, myotonic discharges, which occur in older individuals with myotonic dystrophy, are rarely elicited in the newborn. Muscle biopsy (either by open surgical technique or needle biopsy) is technically feasible in the newborn. Early biopsy may be required if there is severe respiratory muscle involvement to provide definitive diagnosis and prognosis to assist management decisions. Otherwise, muscle biopsy is often postponed for several months, as it may be difficult to interpret in the newborn period. In some instances (e.g. congenital muscular dystrophy), repeated muscle biopsies may be useful for establishing an accurate diagnosis.

SUMMARY

The approach to a newborn with hypotonia should not differ substantially from that to an older child. The

examination may be more difficult, however, history, laboratory studies (serum enzymes, EMG, muscle biopsy), and genetic studies (when indicated) may be helpful in arriving at a diagnosis, even in premature infants.

Long-term Follow-up of High-risk Babies

Praveen Suman

INTRODUCTION

The birth of a baby is an event of joy and happiness for everyone—parents, grandparents, siblings and friends. However, taking a premature baby or a baby who has special needs home from the hospital is both an exciting and overwhelming adjustment for most parents. As you prepare to take your baby home, you may be thinking of his or her future medical and developmental needs. High-risk follow-up programs are specifically designed to monitor the development of children who are at increased risk for emerging delays and it can provide special attention and answers to questions about child's health, growth, nutrition and development. Unlike traditional child-development clinics, which address problems in children who have already been identified as having a delay or disorder, follow-up clinics focus on identifying problems as they emerge. In general, the focus of these clinics is on identification of emerging problems related to neonatal risk factors.

Follow-up Criteria

Children who are considered to be at “high-risk” for developmental problems and those already identified as having developmental concerns require more extensive screening than children at lower risk. Close monitoring of development, together with coordination of treatment for any emerging problems, is often referred to as “developmental follow-up.” Children who are at increased risk for developmental problems include those born very prematurely or at very low birth weight, as well as those with known neurological abnormality at birth and those who are very ill during the newborn period.

Which Children Need Long-term Follow-up?

Babies who need follow-up include:

- Babies with <1800 g birth weight and/ or gestation <35 weeks
- Small for date (<3rd centile) and large for date (>97th centile)
- Perinatal asphyxia: Apgar score 3 or less at 5 min and/ or hypoxic ischemic encephalopathy
- Mechanical ventilation for more than 24 hours
- Metabolic problems: Symptomatic hypoglycemia and hypocalcemia
- Seizures
- Infections: Meningitis and/or culture positive sepsis
- Shock requiring inotropic/vasopressor support
- Major morbidities such as chronic lung disease, intraventricular hemorrhage, and periventricular leukomalacia
- Infants born to HIV-positive mothers
- Twin with intrauterine death of cotwin
- Twin-to-twin transfusion
- Hyperbilirubinemia >20 mg/dl or requirement of exchange transfusion
- Rh hemolytic disease of newborn
- Major malformations
- Inborn errors of metabolism/other genetic disorders
- Abnormal neurological examination at discharge.

DISCHARGE FROM NICU

Discharge planning in the NICU is a multidisciplinary effort that begins with the infant's birth and admission to the unit. Important aspects include the parents' involvement in their infant's care, plans for special needs such as oxygen and apnea monitoring, and teaching the parents special skills.

Social criteria for discharge include the following:

- Confirmation that the parents can provide the basic physical needs of the infant
- Assurance that the parents are knowledgeable about their infant's needs and know how to identify problems that may arise following discharge

- A specified plan for continuing health care and parenting support. The stress parents experience while their infant is hospitalized may interfere with their ability to learn; therefore, parents' education often needs to be reinforced after the infant's discharge. Also, parents should have sufficient help at home to support them in the care of their infant.

Most NICU's have no minimum weight requirement for discharge. Medical guidelines for discharge are as follows:

- Body temperature is maintained while the infant is in an open crib, usually at 34 weeks of gestational age or at 2,000 g (4 lb, 6 oz) of weight
- The infant feeds by mouth well enough to have a weight gain of 20 to 30 g per day
- The infant is not receiving medications that require hospital management
- No recent major changes in medications or oxygen administration have occurred.

Before discharge, premature babies also need an eye examination and hearing test to check for problems related to prematurity. Parents need information about follow-up visits with the pediatrician for baby care and immunizations. Many hospitals have special follow-up healthcare programs for premature and low birth weight babies.

Who can Provide Follow-up Services?

Even though high-risk babies are otherwise ready for discharge, some babies continue to have special needs such as extra oxygen or tube feedings. With instruction and the right equipment, these babies are often able to be cared for at home by parents. A hospital social worker can often help coordinate discharge plans when special care is needed. At a minimum, developmental follow-up for high-risk infants should involve periodic screening for sensory impairment, developmental delays, and any other condition for which an individual infant is considered to be at increased risk. Comprehensive follow-up involves close evaluation of medical, psychological, and social factors in addition to assessment of developmental progress. Children who are suspected of having had neurological injury will need close evaluation of neurodevelopmental functioning to investigate the possibility of long-term impact as their nervous systems mature. The follow-up team also must be able to integrate information from the various specialty physicians, care of each high-risk neonate after discharge must be carefully coordinated to provide ongoing multidisciplinary support of the family. The discharge planning team should include parents, the primary care physician, the neonatologist, social worker, developmental pediatrician, pediatric occupational, physical, speech, and respiratory therapists, nutritionists are included as needed.

Pediatricians may incorporate developmental follow-up into their routine well-child care. Administration of a brief screening instrument requires an additional 10 to 15 minutes of examination time. More time is required for children who do not pass an initial screening. Coordination of additional tests, specialty services, and therapies, is necessary when delays or impairments are identified. When problems are identified on initial screening, pediatricians may choose to refer the family for further evaluation and follow-up (child development clinic, or to a specialized follow-up program for high-risk).

When to Follow-up?

- Infants with <1800 g birth weight and/or gestation <35 weeks:
 - Follow-up after 3 to 7 days of discharge to check if the baby has been adjusted well in the home environment. Every 2 weeks until a weight of 3 kg (immunization schedule until 10 to 14 weeks to be covered in these visits)
 - Follow-up at 3, 6, 9, 12 and 18 months of *corrected* age and then every 6 months until age of 8 years.
- All other conditions:
 - Follow-up—2 weeks after discharge
 - At 6, 10, 14 weeks of postnatal age
 - At 3, 6, 9, 12 and 18 months of *corrected* age and then every 6 months until age of 8 years.

ASSESSMENT OF FEEDING AND DIETARY COUNSELING

Caloric intake, fluid intake, and vitamin and mineral supplementation should be monitored during weekly visits. Nutritional requirements in the NICU are usually 120 kcal per kg per day. This amount usually drops to 100 kcal per kg per day by the time of discharge.

Breast milk protects against infection, and breastfed infants have better developmental scores at 18 months of age than formula-fed infants. Mothers who plan to breast-feed should use a hospital-quality electric breast pump after the infant's birth to stimulate their breasts. The pumped milk may be fed to the infant. When the infant is able to suckle, the mother should start breastfeeding to further encourage milk production. By the time of discharge from the hospital, most premature infants require feedings at least every three hours. Human milk fortifier (a supplement that is added to pumped breast milk) should be used as advised by the NICU.

If there is a question about the mother's supply of breast milk, she should nurse every one and one-half to two hours during the day in the first 24 to 48 hours after the infant's discharge to ensure adequate milk production. After this initial period, the infant is normally nursed every two to three hours, or eight to 10 feedings per day.

Six to eight wet diapers per 24 hours indicate an adequate fluid intake. Fluid should not be withheld for longer than four hours.

Solid food should be introduced at four to six months past the infant's due date. The infant's swallowing mechanism will not accept or handle solid food until two and one-half to three and one-half months past the infant's due date. Sick infants, such as those with bronchopulmonary dysplasia, often require special dietary intervention. In this instance, coordination between the dietary staff and other care providers is necessary.

VITAMINS AND MINERALS

Vitamins D, E and K, and folic acid are especially important for low birth weight infants. Except for vitamin D deficiency, vitamin deficiencies are unlikely to occur after discharge from a neonatal intensive care center. The signs and symptoms of vitamin D deficiency are enlarged costochondral junctions (rachitic rosary), bowlegs and knock knees (which usually develop after the child has started walking), failure to thrive, hypocalcemia, and hypophosphatemia.

Although vitamin deficiencies are rare, all breastfed infants should probably receive vitamin supplementation during the first year of life. Standard dose of infant vitamins that provides 400 IU of vitamin D per day is advised for both premature and term infants. If a special formula is used, its vitamin content should be checked to determine if supplementation is required.

Supplemental iron is advised, either as iron-fortified formula or as a liquid, given in a dosage of 2 to 4 mg per kg per day in breast-fed infants or infants receiving low-iron formulas. Iron supplementation should be started two weeks to two months after birth and continued for 12 to 15 months. The infant should receive 0.25 mg of fluoride supplementation daily if the water in the household is not fluoridated. Many dental problems, including enamel hypoplasia, dental caries and delayed dental development, are reported to be more common in preterm infants than in term infants.

Although rare, deficiencies of zinc and copper have been reported in premature infants at three to six months of age.

IMMUNIZATIONS

The timing of immunizations should be based on the infant's chronologic age, not the gestational age. The only exception is hepatitis B vaccination. The American Academy of Pediatrics Committee on Infectious Diseases has issued a statement indicating that it may be advisable to delay administration of hepatitis B vaccine until the infant weighs 2,000 g. The full dose of all immunizations should be given.

GROWTH MONITORING

During the first two years of life, growth is plotted using age corrected for prematurity. Growth charts for the "average" premature infant have been designed for this purpose. Special neonatal growth charts are also available for the sick or small-for-gestational-age infant. After the infant reaches two years of age, a standard growth chart for chronologic age may be used.

Many premature infants have catch-up growth. Catch-up growth is usually first noted in the infant's head circumference, followed by the infant's weight and length. This usually occurs during the first two to three years of life and is maximum at 36 to 40 weeks after conception. Little catch-up growth occurs after three years of age. Premature infants with intrauterine growth retardation and no catch-up growth have a higher risk of developmental delay and other medical problems than premature infants with a normal growth rate. Even in adolescence, children who were born prematurely may be smaller than children not born prematurely. Menarche also occurs later in girls who were born prematurely. One study showed that women who were born prematurely are more likely to deliver premature infants themselves. Another study found a trend for this to happen, but it was not statistically significant.

Catch-up Growth

However, for the child to become the same size as his or her full term peers, growth will have to be faster than usual. This is called "catch-up growth".

85% of premature infants have catch-up growth and land on the regular growth chart by two years of age.

Delays in catch-up growth—Some common reasons a child may not catch-up fully by two years of age are:

- Starting out very far below the growth chart with a long, long way to catch-up
- Ongoing problems, which increase the nutritional requirements
- Some babies (but not all) with BPD or chronic lung disease may have an increased metabolic rate and need more nutrition than other infants. This increased metabolic rate can also last for a long time after discharge. Another potential ongoing problem is illness and a reduction in feedings as a result. Some children with cerebral palsy also have higher metabolic rates. There are other ongoing problems, which might apply, as well
- Poor appetite

A few other studies have looked at long-term growth. *The bottom line is that catch-up growth can continue into adolescence, and the majority of tiny premature infants should be normal sized adults.*

Neurodevelopmental Follow-up of High-risk Neonates

In a time when health care is increasingly rationed, the cost of acute and long-term care for VLBW infants is a controversial subject. These infants frequently require months of care in an intensive care unit, and there is concern that their increased survival may be accompanied by a higher incidence of physical, neurologic, sensory, and developmental handicaps. As more infants survive, neonatal specialists are faced with evaluating the effectiveness of these changes in treatment.

Improvements in neonatal care have had a significant impact on infant mortality rates in the 20th century. Several changes in neonatal care have occurred in the second half of this century that have resulted in improved survival of LBW preterm infants. Refinements in the use of oxygen and incubators in the 1940's and 1950's; improvements in thermoregulation in the 1960's; development of neonatal intensive care units and ventilators in the 1970's; and the use of high-frequency ventilators, surfactant, and regionalized care in the 1980's and 1990's, have substantially improved the premature neonate's chances of survival. The increase in the survival rate of infants considered LBW (less than 1,500 g) and VLBW (less than 1,000 g) has led investigators to assess carefully the quality of life of these survivors.

Increased Vulnerability

The preterm infant's neurologic system is at increased risk because it is immature anatomically, chemically, and physiologically. The migration of neurons to the cerebral cortex is generally complete by around 20 weeks' gestation; however, the gray and white matter is poorly differentiated, and the neurons have not reached functional maturity. Synaptic-dendritic organization and myelination is just beginning in the third-trimester. Neurologic function and response occur at the cord and brainstem level, with little inhibition from the immature cerebral structures. The preterm infant is not capable of fully modulating extrauterine stressors. Sympathetic function is generally not seen until 32 weeks' gestation, and autonomic regulation is usually not achieved until 35 to 36 weeks' gestation.

The vascular germinal matrix surrounding the cerebral ventricles is just beginning to mature at 18 to 20 weeks' gestation, and full maturation is not reached until 35 to 36 weeks. The friability of this area and poor vascular regulation during the period of maturation, place the preterm infant at increased risk for the development of an intraventricular hemorrhage or periventricular leukomalacia.

The neurosensory system is also immature. Retinal vascular maturation does not occur until close to term, and rod and cone development is not complete until several months after the infant reaches term. This retinal immaturity places the preterm infant at risk for the development of retinopathy of prematurity (ROP) and possible visual impairment. Neurologic immaturity, coupled with

neurosensory stressors, can have significant long-term effects in the preterm infant.

Risk Factors for Neurodevelopmental Delay

In addition to birth weight and gestational age, numerous intrauterine and extrauterine factors may place a preterm infant at increased risk for neurodevelopmental impairment. Factors most commonly cited include: economic and social-environmental factors; physiologic factors, such as intraventricular hemorrhage, periventricular leukomalacia, chronic lung disease, ROP, and ototoxicity; and the neonatal intensive care environment.

Economic and Social-Environmental Risk Factors

Economic and social-environmental risk factors are the most frequently reported predictors of neurodevelopmental outcome. The possibility of poor neurodevelopmental outcome is heightened when these factors are combined with medical and neurologic risk factors.

Intraventricular Hemorrhage

The presence of intraventricular hemorrhage increases the risk of neurodevelopmental sequel. The severity of the intraventricular hemorrhage is usually graded from 1 to 4, with Grade 4 the most severe. The higher the grade of intraventricular hemorrhage, the more likely are neurodevelopmental problems such as cerebral palsy or mental retardation may occur.

Periventricular Leukomalacia

The area surrounding the ventricles of a LBW infant is particularly susceptible to injury. Ischemia in this area may lead to permanent damage, referred to as periventricular leukomalacia. The areas of the brain most commonly affected are the motor and visual tracts, although other areas may also be affected. Periventricular leukomalacia may also be graded according to severity: mild, moderate, or severe. The greater the severity the higher is the risk for sequel. A child with periventricular leukomalacia is at increased risk for cerebral palsy, mental retardation, and visual impairment.

Neonatal Intensive Care Environment

In recent years, stressors that face the infant in the environment of the neonatal intensive care unit (NICU) have been implicated in long-term developmental problems. The effects of tactile stimulation, noise, light, and absence of diurnal rhythms frequently encountered in an intensive care unit and their impact on the immature neurologic system have been evaluated by numerous researchers.

Retinopathy of Prematurity

Retinopathy of prematurity is an additional risk factor for neurosensory impairment. It is a disorder that disrupts

the normal maturation of the retina and can place the premature infant at increased risk for visual impairment. Maturation of the retina is generally not complete until 40 to 44 weeks gestation. Until then, retinal vessels are vulnerable to injury.

Ototoxic Factors

Numerous factors have been identified as potential causes of permanent hearing damage: environmental noise; low birth weight; hypoxia; use of such ototoxic medications as gentamicin, kanamycin, or furosemide; congenital infection; prolonged assisted ventilation; hyperbilirubinemia; and meningitis. These factors, alone or in combination, may play a role in the development of sensorineural hearing loss in the premature infant.

Importance of Neurodevelopmental Assessment in High-risk Babies

When neurodevelopmental impairment is diagnosed, a common misconception is that the child is always severely affected. It is for this reason that some researchers use the terms major and minor to refer to the severity of a child's disability. Types of neurodevelopmental impairment: major, referring to cerebral palsy, mental retardation, visual impairment, and hearing loss; and minor, referring to cognitive and learning deficits, neuromotor deficits, behavioral, and emotional abnormalities.

An encouraging finding in outcome studies of preterm infants is that the majority of LBW infants survive with little or no disability. In results of studies of neonates weighing less than 1,500 g, 62 to 80 percent have been reported as normal, 16 to 21 percent as having mild or moderate disability, and 5 to 12 percent as having severe disability. The lower the gestational age, however, the higher the incidence of major disability. Minor disability rates are reported at 15 to 25 percent for the VLBW infant. Children may exhibit more than one minor or major disability.

MAJOR NEURODEVELOPMENTAL IMPAIRMENTS

Cerebral Palsy

The incidence of cerebral palsy (CP) in the preterm population is generally reported as 6 to 10 percent. The most common form of CP found in the preterm population is spastic diplegia. Cerebral palsy is non-progressive; a child with a mild form will not progress to a more severe form. A child with CP is at higher risk for mental retardation or learning disabilities, particularly if CP is severe; but it is important to note that many children with CP have normal cognitive skills.

Mental Retardation

The incidence of mental retardation in the preterm population is generally reported at 4 to 8 percent. Mental

retardation varies in severity, with mild referring to both measurements of adaptive function and IQ scores between 50 to 70; moderate, 35 to 55; and severe or profound, less than 40. Most preterm infants diagnosed with mental retardation are in the mild to moderate range.

Visual Impairment

Visual impairment in the preterm population is generally a result of ROP. Retinopathy of prematurity is reported to occur in approximately 80 percent of infants with birth weights 750 to 1,000 g and in 90 percent of infants with birth weights less than 750 g. Retinopathy of prematurity, even if mild and fully regressed, places the preterm infant at higher risk for later visual sequel. The most common sequel of ROP includes myopia, strabismus, and amblyopia.

Hearing Loss

The incidence of neurosensory hearing loss in the preterm population is generally reported at 1 to 6 percent. Hearing loss is usually in the mild to moderate range (26 to 55 dB), with complete deafness atypical. A hearing loss of 30 dB or more in the speech-frequency range (500 to 4,000 Hz) will interfere with the normal development of speech.

Minor Neurodevelopmental Impairment

Minor neurodevelopmental problems include cognitive deficits, learning deficits, behavioral difficulties, and subtle neuromotor deficits. Although termed minor, impairments in this category can have a substantial impact on the life of a premature child.

Cognitive Deficits

Subtle cognitive deficits have been found in results of some studies comparing performance of school-age LBW preterm children with that of full-term children. Although mean IQ's were still in the average range (100 ± 15), the mean IQ of LBW children has been reported to be 8 to 10 points lower than the mean IQ of full-term children. Borderline intelligence, defined as having measurements of adaptive functioning and IQ scores between 70 and 84, has been reported in one-fifth of those with birth weights 750 to 1,500 g and in one-third of infants with birth weights less than 750 g. Because this problem can easily go undiagnosed, children in this category are at greatest risk of receiving educational services that do not meet their needs.

Learning Deficits

Although the incidence of learning disabilities in the LBW population is unclear, partially because of differences in defining terms, the widespread prevalence of these difficulties is clear in results of outcome studies in school-age children. In findings in a study of 8-year-old LBW children, 45 percent reported having difficulty with one or more subjects in school, compared with 11 percent of full-term children reporting such difficulties.

Deficits in reading, spelling, and math skills are more common in LBW children. Language deficits, which result in difficulty with receptive comprehension, expressive vocabulary and word retrieval as well as in articulation and fluency, are also more common in LBW children. In the classroom setting, these children may seem to follow directions poorly, may have difficulty comprehending reading and may avoid classroom participation. Visual-perceptual-motor problems are also more common. In addition to weaknesses in fine motor control, finger agnosia, and motor planning LBW children are more likely to have difficulties in sequencing, in organizing visual information, and in visual motor integration. These problems become evident when a child is asked to write by hand, arrange pictures, assemble objects, or copy designs. Deficits in cognitive functioning have also been reported and include difficulty in memorization, in logical and abstract thinking, and in spatial relations. In the classroom setting, children with these deficits demonstrate difficulties in using common sense, managing new information, remembering assignments, and making decisions.

Behavioral Difficulties

Low birth weight children are more likely to exhibit deficits in results of measurements of adaptive behavior than are full-term children. Impulsive behavior, distractibility, poor attention span and autistic spectrum disorder are reported with a higher frequency. Difficulties with self-control when making transitions between activities, over aggressiveness in play, noncompliance with requests, and difficulty in parental separation are also reported. In reported results of studies, attention deficit disorder and hyperactive behavior occurs more frequently in preterm children (7%) than they do in control subjects (1%). An increased frequency of depressed behavior and internalizing behavior (i.e. timidity, passivity, and anxiety) has also been reported

Subtle Neuromotor Deficits

LBW school-age children: One-third of children with birth weights less than 1,500 g demonstrate poor gross motor skills in standardized testing. Difficulties with balance, coordination, and postural control have been reported. In a survey of teachers, responses showed that LBW children were more likely to be identified as having less athletic competence than their full-term classmates. These gross motor difficulties can affect a LBW child's ability, as well as desire, to enter into playground activities or sports with peers.

What should Neurodevelopmental Follow-up Involve?

Information about the developmental needs of the high-risk infant should be provided to NICU parents through group classes, handouts, or videos. It is also important

to individualize the education plan to encompass specific cultural needs in each family. Parental involvement is considered vital to the implementation of developmental care. Parents must be able to interpret their child's behavioral cues and learn how to respond appropriately. Screening tests designed for initial screening in the general population should not be relied upon for the identification of delays in children known to be at high-risk for developmental problems. When used with groups of high-risk children, such tests do not have a satisfactory rate of accuracy in identifying developmental problems. It is also not appropriate to use screening tests to "rule out" problems about which parents have voiced a concern. That is, passing a screening test should not be used as an indication that there is no problem when there is cause for concern due to the child's early history and/or parent report of unusual behavior. When children are known to be at high-risk for developmental problems or when parents have noted something worrisome about their child, more in-depth evaluation is needed.

Development Assessment

The infant's development during the first two years should be plotted from the infant's estimated due date rather than the infant's birth date. The Denver Prescreening Developmental Questionnaire, the Denver Developmental Screening Test and the Gesell Screening Inventory are all accepted tests. Using a standardized developmental test is more important than the choice of test.

Developmental screening does not replace the neurologic examination. Because of this, detailed standardized examinations, such as the Neonatal Neurodevelopmental Examination, have been developed. The latter has been used primarily by developmental pediatricians and pediatric neurologists. It assesses postural reflexes and muscle tone, cranial nerve and motor function, sensory responses and behavior. If an abnormal finding is noted, such as neck extensor hypertonia, consultation with a developmental specialist should be considered.

In an attempt to prevent disabilities, a number of intervention programs have been developed and evaluated. These include interventions in the neonatal nursery, at home and at special centers. A review of various intervention programs for low-birth-weight infants, all evaluated since 1971, found that intervention programs provide support and improve parent child interaction. Most NICU's have developmental follow-up programs, and the physician should encourage the parents to participate in these programs. The most severe diagnoses are usually evident by ages 2 to 4 (CP, major retardation, blindness, deafness). The less severe diagnoses (low or mildly retarded IQ, learning and behavior problems, mild visual and hearing problems and problems with hearing and visual processing) are not always known till age 8 to 11 or even later. There are even some problems that may not

show up till late adolescence or adulthood—e.g. seizures, or late loss of vision from ROP.

Vision and Hearing Assessment

Strabismus is more common in premature infants than in term infants. Because strabismus can be a sign of intraocular pathology, ophthalmologic consultation is generally indicated in infants with strabismus. In many very-low-birth-weight infants, strabismus at six weeks of age resolves by the time the infant reaches nine months of age. Strabismus that is present at nine months of age is likely to persist.

Retinopathy of prematurity occurs in some infants born at 32 weeks of gestation or less, and evaluation for this condition will already have taken place in the NICU. The American Academy of Pediatrics, the American Association for Pediatric Ophthalmology and Strabismus, and the American Academy of Ophthalmology recommend obtaining an initial screening examination at four to six weeks' chronologic age, with follow-up examinations performed as required on the basis of the initial findings.

Most NICU's obtain brainstem auditory evoked potential testing before the infant's discharge. Hyponatremia, metabolic alkalosis and prolonged mechanical ventilation with high oxygen concentrations are risk factors for hearing loss. The use of an aminoglycoside or furosemide is an additional risk factor. The World Health Organization defines hearing loss as an average loss of greater than 25 dB at frequencies of 500, 1,000 and 2,000 Hz, classified according to the less impaired side. Using this definition, about 5 percent of premature infants born before 32 weeks of gestational age have hearing loss by five years of age. Parents should be asked if they notice signs of hearing impairment in their infant. The infant's response to loud noise can be checked in the physician's office, and receptive and expressive language can be assessed with a developmental screening tool. Audiologic consultation should be obtained if the parents notice signs of hearing loss or if findings on the screening procedure are abnormal.

SUMMARY

Changes in neonatal care have resulted in an increase in the survival rate of LBW infants, with most preterm infants surviving without neurodevelopmental impairment. However, although it is nearly impossible to predict directly the type and severity of an individual child's neurodevelopmental problems, the lower the birth weight, the higher the risk for impairment. In addition, an increase in the severity of disability can be seen with decreasing birth weight. Fortunately, most problems in the preterm population are mild to moderate, and although LBW infants are faced with a higher rate of morbidity than that of their full-term counterparts, results of a recent study of

adolescent VLBW infants showed that most viewed their health-related quality of life as quite satisfactory. Because more LBW infants are surviving, the specialist team is challenged with determining and providing care that minimizes the neurodevelopmental problems seen in preterm infants.

CHAPTER 30

Approach to a Newborn with Suspected Cardiac Disease

Neeraj Aggarwal, Manvinder Singh Sachdev

INTRODUCTION

A newborn with cardiac disease can have variable presenting features. Also most of these presentations can mimic the common neonatal disorders such as septicemia, shock, respiratory disorders, persistent pulmonary hypertension of newborn (PPHN), inborn errors of metabolism and so on. But with a meticulous approach, working cardiac diagnosis can be made and appropriate management started.¹ This chapter emphasizes the approach to common neonatal cardiac disorders and management of various clinical scenarios which a neonatologist comes across in his day to day practice.

HISTORY

Detailed medical history about antenatal and perinatal events is very important to determine the possibility of cardiac disease. In today's world where antenatal diagnosis is getting more and more precise and fetal echo is providing great insights into the disease, neonatologist must inquire about these reports.² Similarly, antenatal history about drugs and diseases may point to a specific diagnosis and should be sought. Perinatal events leading to respiratory distress and cyanosis at birth may point to the diagnosis of non-cardiac cause of cyanosis and uneventful delivery with sudden onset of cyanosis or shock after 24 to 48 hours of birth should give a suspicion of duct dependent circulation. A history of preterm baby with hyaline membrane disease getting better after surfactant therapy and then again worsening with need for ventilator is a good pointer to look for patent ductus arteriosus (PDA). One more common feature in preterm babies is apnea followed by cyanosis which is perceived as gastroesophageal reflux related episode, may also be due to a hemodynamically significant PDA. Any neonate who presents within first two weeks of life with sudden onset of unexplained

collapse or cyanosis must be suspected for a duct dependent cardiac disease.

EXAMINATION

Neonatal cardiac examination alone may not give complete information but with an insight of cardiology, this examination can be fruitful enough to have a working differential and with the help of chest X-ray and ECG, can point to a specific cardiac etiology. Dymorphology may point towards a syndrome and help in diagnosing a heart lesion. Down's syndrome is a well known example where cardiac defects are known to occur with high frequency in particular atrio-ventricular canal defects (AVCDs). Examination of upper and lower limb pulses and BP is a critical step in diagnosing coarctation of aorta where there are normal heart sounds and no murmur. Absent lower limb pulses, radiofemoral delay or upper limb hypertension will diagnose a coarctation. Systolic BP of upper limbs more than 10 mm Hg than the lower limbs suggests coarctation of aorta. Again if PDA is large in such cases, this feature of coarctation will be absent as large PDA will supply the descending aorta. In such scenario lower limb desaturation will help to diagnose. Low volume pulses in all extremities will suggest left-sided obstructive lesion like aortic stenosis. Similarly, bounding pulses will be felt in PDA, aortic regurgitation, truncus arteriosus and systemic arteriovenous fistula.

Pulse oximetry can be a valuable tool and important assistant to clinical examination. Naked eyes can not diagnose cyanosis in patients where saturation is less than 85 percent and so will miss cyanotic heart disease in many cases unless pulse oximetry is used. This may be a valuable exercise to diagnose cyanotic heart diseases in newborn and may be a routine in our neonatal units soon.³ The best time would be after 24 hours of life as many normal neonates will have lower saturation in first 24 hours of life.

Fig. 1: Chest X-ray of a neonate with situs solitus, dextrocardia where high possibility of a complex cardiac lesion should be kept

The cardiac examination should be performed in a systematic manner. Situs solitus with dextrocardia should point towards a complex cardiac lesion (Fig. 1). Left-sided precordial bulge will suggest cardiac enlargement and a left parasternal heave indicates right ventricular hypertension. Also look for a palpable precordial thrill. Any of these additional findings in the term infant with a heart murmur suggest pathologic murmur. Abnormalities of the second heart sound are often seen in congenital heart disease, making it perhaps the most important element of auscultation in the pediatric patient. Third and fourth heart sounds can be normal. The Grades IV, V, and VI murmurs are associated with a palpable precordial thrill, and are always pathologic. The innocent murmurs are soft (Grades I or II) and ejection in quality. Although diastolic murmurs are much less common in the child, the auscultation of a diastolic murmur indicates that structural heart disease is present.

Last, a simple, noninvasive indicator of cardiac output is the capillary refill time. This is obtained by blanching the nail bed or digit, and observing the time to reperfusion, normally less than 3 seconds.

HEMODYNAMIC CONSIDERATIONS IN NEONATE⁴

Neonates are born with pulmonary arterial hypertension and this makes the assessment of left to right shunts difficult by clinical examination or echocardiography. Appearance of murmur in left to right shunts is delayed for 2 to 3 weeks till the pulmonary vascular resistance drops. This change in hemodynamic is also important for many critical cardiac evaluations. Some examples are important to consider here. A small or moderate ventricular septal

defect (VSD) will not have a PSM at birth (characteristic of a restrictive VSD shunt) due to high PVR and ECHO may not show volume overload of Left atrium and left ventricle and pulmonary pressures will always be high enough to cause confusion in the estimation of true hemodynamics of VSD shunt till 2 to 3 weeks of age. In such cases it is mandatory to repeat echo after 2 to 3 weeks to assess such patients. Similarly, right-sided obstructive lesions may be under diagnosed in neonatal period with presence of PAH (like pulmonary stenosis and TOF physiology) where gradient across pulmonary valve will be underestimated in presence of pulmonary hypertension and such cases will need follow-up evaluation after 1 to 2 weeks to reassess the severity of true obstruction by Doppler.

CLINICAL PRESENTATIONS IN NEONATE⁵ (TABLE 1)

Neonates with cardiac disease can vary in their presentations and most of these manifestations can be seen in more common neonatal disorders including septicemia, PPHN and congenital respiratory disorders. With a meticulous examination and following a standard approach for the neonate, it can help in identifying the neonate with cardiac disease and also in management of the critical disease.⁵⁻⁷

TIMING OF PRESENTATION

Timing of presentation of neonates helps in identifying the cause and initiation of timely therapy. Normally, the duct closes after 24 to 48 hours of life and so a clinical clue can be drawn from the time of onset of symptoms. If a newborn presents immediately after birth with shock or cyanosis, this can be regarded as non-duct dependent lesion and other causes should be sought. We have come across many such situations where prostaglandin was started within first two hours of life for cyanosis and subsequent echo showed normal cardiac anatomy. Although this will also happen in many instances where prostaglandin is started empirically after 48 hr of life, it should always be remembered that starting prostaglandin is justified and there are no major adverse effects and it can always be discontinued once an echocardiogram has ruled out duct dependent lesion. Keep a low threshold to start prostaglandin in suspected duct dependent lesion even if the patient is stable because there rapid deterioration will be seen once the duct closes.⁸ There is increasing evidence that starting prostaglandin empirically has better outcome than not starting it.

Lesions which present in first 48 hours of life are critical left-sided obstructive lesions like hypoplastic left heart syndrome, interrupted aortic arch, critical aortic stenosis and obstructed TAPVC, bradyarrhythmias. Later in the first week, coarctation of aorta and duct dependent lesions may present.^{5,7} Also, obligatory shunts (which

Table 1: Clinical presentations in neonates with congenital heart disease**Shock***Duct dependent systemic circulation and left ventricular outflow tract obstructions*

- Critical aortic stenosis
- Interrupted aortic arch
- Severe coarctation of aorta
- Hypoplastic left heart syndrome (HLHS)

Rhythm disturbances

- Tachyarrhythmias
- Bradyarrhythmias (e.g. complete heart block)

Cyanosis*Duct dependent pulmonary circulation*

- Pulmonary atresia, intact ventricular septum
- Pulmonary atresia, VSD and PDA
- Single ventricle with pulmonary atresia
- Severe forms of Ebsteins anomaly

Critical right ventricular outflow tract obstruction with intracardiac shunt

- Critical pulmonary stenosis with interatrial communication
- Tetralogy of Fallot with critical pulmonary stenosis
- Double outlet right ventricle, VSD with pulmonary stenosis

Admixture lesions

- Transposition of great arteries, intact interventricular septum
- Total anomalous pulmonary venous connection
- Truncus arteriosus
- Double outlet right ventricle with VSD
- Single ventricle anomalies with or without pulmonary stenosis

Congestive heart failure*Cyanotic heart disease with high pulmonary flow*

- Truncus arteriosus
- Single ventricle physiology without pulmonary stenosis
- Transposition of great arteries with VSD
- Double outlet right ventricle with VSD
- Total anomalous pulmonary venous connection

Acyanotic heart disease

- Preterm with significant post-tricuspid shunt lesions (e.g. VSD, PDA, aortopulmonary window)
- Severe valvular regurgitant lesions (e.g. mitral regurgitation associated with AV canal defects or isolated mitral regurgitation, aortic regurgitation)
- Anomalous left coronary artery from pulmonary artery (ALCAPA)
- Cardiomyopathy

Rhythm disturbances

- Tachyarrhythmias
- Bradyarrhythmias (e.g. complete heart block, high degree second heart block)

Noncardiac causes

- High output states like anemia, thyrotoxicosis, systemic Arteriovenous malformations (i.e. vein of Galen)

Asymptomatic newborn with murmur

- Mild to moderate obstructive lesions (aortic stenosis, pulmonary stenosis)
- Mild to moderate regurgitant lesions
- Physiological murmurs (including peripheral pulmonary stenosis)
- Left to right shunt lesions

don't depend on pulmonary vascular resistance) such as left ventricular to right atrial shunt also present in the first week of life. Later in the first week or in second week, cyanotic heart lesions with high pulmonary blood flow may present with Congestive heart failure where as acyanotic left to right shunts (post-tricuspid lesions like VSD, PDA, and aortopulmonary window) usually present beyond 2 to 3 weeks of age. These shunts are nonobligatory (shunts which depend on pulmonary vascular resistance) and so present only when pulmonary vascular resistance falls. Although, it must be remembered that overlap exists in the timing of presentation of these cases and coexisting diseases in such cases may lead to earlier presentation.

Neonates Presenting with Cardiovascular Collapse

The most important diagnosis in such cases is obstructive lesions like critical Aortic stenosis (AS), critical coarctation with left ventricular dysfunction and also critical pulmonary stenosis (PS) with RV dysfunction. This also includes cases of hypoplastic left heart syndrome (HLHS) and obstructive TAPVC (total anomalous pulmonary venous connection) who present in shock.

Neonates presenting with sudden onset of shock after 48 hr of life may be all the above cases (critical AS, critical PS, coarctation, HLHS, obstructive TAPVC) and also duct dependent circulation which present after duct closure with collapse.

This neonate is usually a healthy newborn who presents after 48 to 72 hr of life with sudden onset of pallor, gray appearance and breathing difficulty. Parents complain that baby is not passing urine and not taking feeds over last 4 to 6 hr. There is usually an evidence of metabolic acidosis. These newborns should be started immediately with prostaglandin E1 suspecting duct dependent systemic circulation among other measures to stabilize including ventilation and inotropes (unless echo rules out cardiac lesion).

If duct is still open these newborns may be picked up during routine evaluation with a harsh systolic murmur of obstructive lesion (aortic stenosis or pulmonary stenosis). Coarctation of aorta will be picked up by careful palpation of all 4 limb pulses and blood pressure. Any evidence of radio femoral delay should prompt the diagnosis of coarctation of aorta. Differential cyanosis with lower limb showing desaturation compared to upper limb should prompt for the cause of PDA shunting right to left (e.g. interrupted aortic arch, severe coarctation of aorta or PPHN) (Fig. 2).

ECG must be done in all neonates presenting with shock to detect arrhythmias in the neonates. Supraventricular and ventricular tachycardia, or extreme bradycardia, can be associated with pallor, diaphoresis, dizziness, and syncopal or pallid spells, all related to the decreased

Table 2: Noncardiac causes of cyanosis in the neonate		
Pulmonary		
Primary lung disease	Airway obstruction	Extrinsic compression of the lungs
Respiratory distress syndrome, meconium aspiration, persistent pulmonary hypertension of the newborn, pneumonia, tracheo-esophageal fistula	Choanal atresia, laryngotracheomalacia laryngeal web, vocal cord para-lysis	Pneumothorax, chylothorax, hemothorax, diaphragmatic hernia, space occupying lesions in lungs
Neurologic		
CNS dysfunction	Respiratory neuromuscular dysfunction	
Drug-induced depression of respiratory drive, intracranial hemorrhage, post-asphyxial cerebral dysfunction, or central apnea	Spinal muscular atrophy, infant botulism, or neonatal myasthenia gravis	
Hematologic		
Methemoglobinemia or polycythemia		

Fig. 2: Schematic description of a interrupted aortic arch where there is no forward flow from arch into the aorta. PDA supplies blood from pulmonary artery to descending aorta which is a deoxygenated blood explaining the lower limb desaturation (arrows depict direction of blood flow). If PDA closes in this case, there will be no blood supply in the descending aorta and patient presents with shock

cardiac output. Occasional premature atrial or ventricular contractions are usually benign findings in the newborn.

Newborn Presenting with Cyanosis^{5,7,9}

Cyanosis in a newborn is a serious sign and can occur due to cardiac and noncardiac causes. Peripheral cyanosis must be differentiated from central cyanosis. Peripheral cyanosis (acrocyanosis) results from peripheral vasoconstriction or autonomic disturbances and may last for few days after birth. This may also happen after exposure to cold. Central cyanosis is characterized by bluish discoloration of tongue or mucous membranes. Pulse oximetry will help in the diagnosis of central cyanosis with a high degree of

accuracy. It must be remembered that murmurs may be absent or non-specific in many cases of cardiac cyanosis.

The causes of central cyanosis in the newborn are of cardiac, pulmonary, neurologic, or hematologic origin (Table 2). This is important to differentiate the cardiac causes from noncardiac ones. Clinical clues to diagnosis of respiratory central or cardiac causes of cyanosis in a newborn can be drawn from the respiratory pattern, pulse oximetry in right upper limb and lower limbs and response to oxygen on pulse oximeter (Table 3).

Differential Cyanosis

Pulse oximetry should be documented at preductal and postductal sites to assess for differential or reverse differential cyanosis. If the preductal saturation is higher than the

Table 3: Differential diagnosis in a cyanotic neonate				
Parameters	Respiratory pattern	Saturation difference between right upper limb (RUL) and lower limb (LL)	PCO ₂	Response to 100% oxygen
Cardiac disease	Increased respiratory rate with no or minimal distress	Usually no difference unless specific lesions	Normal or low	No significant change
Primary pulmonary disease	Increased respiratory rate with distress	No difference	High	Increased saturations
PPHN	Increased respiratory rate with distress	>10% RUL>LL	Normal or high	May or may not change
CNS disorder	Shallow respiration or apnea, hypotonia and lethargy	No difference	High or low	No significant change

PPHN: Persistent pulmonary hypertension of newborn

postductal saturation, differential cyanosis exists, which results when there are normally related great arteries and deoxygenated blood from the pulmonary circulation enters the descending aorta through a PDA. Differential cyanosis is seen in persistent pulmonary hypertension of the newborn (PPHN) and in lesions with left ventricular outflow tract obstruction such as interrupted aortic arch, critical coarctation of the aorta and critical aortic stenosis.

In rare cases of reverse differential cyanosis, the postductal saturation is higher than the preductal saturation. This occurs only in children with transposition of the great arteries (TGA) with left ventricular outflow obstruction (i.e. critical coarctation of the aorta, interrupted aortic arch, critical aortic stenosis) or TGA with PPHN. Oxygenated blood from the pulmonary circulation enters the descending aorta through PDA.

Cardiac Causes of Cyanosis

These are usually healthy neonates who present with sudden onset of cyanosis after being well for 2 to 3 days when PDA starts constricting or it may be picked up during evaluation when soft faint murmur of PDA (for example Pulmonary Atresia, VSD as shown in Figure 3) may be heard and saturation of baby reveals central cyanosis. Newborns with TGA will present with mild tachypnea without respiratory distress with saturation of around 90 percent (it should be remembered that naked eyes may not pick up cyanosis where saturation is above 85 percent, so always pulse oximeter should be used to determine cyanosis).

Fig. 3: Schematic diagram illustrating the aortic pulmonary valve with a VSD. There is no antegrade blood flow across pulmonary valve from right ventricle and PDA supplies blood to pulmonary circulation. Arrows depict the direction of blood flow from aorta to pulmonary artery through PDA

There is obviously no response to oxygen in such cases and hyperoxia test fails. Although, it should be remembered that its not necessary to conduct hyperoxia test before starting prostaglandin especially if child has sudden onset of desaturation after being well for first 48 hr of life.

Chest X-ray (Figs 4 to 7) should be obtained as soon as possible to rule out respiratory issues. It will help in assessing the pulmonary blood flow and presence of cardiomegaly. Increased pulmonary blood flow with cardiomegaly will suggest the possibility of TGA (egg on string appearance), truncus arteriosus (high pulmonary artery take off) or unobstructed TAPVC where as pulmonary edema without cardiomegaly will suggest obstructed TAPVC. Reduced pulmonary blood flow with no or minimal cardiomegaly will point to duct dependent pulmonary circulation or critical RVOT obstructions with intracardiac mixing. Massive cardiomegaly with reduced pulmonary blood flow will suggest a diagnosis of Ebstein anomaly. ECG will also be helpful in identifying the type of disease. Tricuspid atresia will have superior axis, Critical PS or PA/IVS will have axis in 0 to 90 quadrant whereas TOF will have axis 90 to 180.

Hyperoxia Test

A hyperoxia test should be used in a neonate to differentiate mainly cardiac from respiratory illness and is performed when resting saturations are less than 95 percent. It is performed with administration of 100 percent O₂ through head mask for 10 minutes. Direct arterial blood gas sample is taken from right upper limb (preductal) and

Fig. 4: Chest X-ray of transposition of great arteries. Note the narrow upper border of mediastinum (due to anteroposterior relationship of great arteries and absence of thymus) and classical egg on string appearance. There is clear evidence of high pulmonary blood flow

Fig. 5: Chest X-ray showing cardiomegaly with high pulmonary blood flow and narrow upper border of mediastinum. There is a high take off of pulmonary arteries suggesting possibility of truncus arteriosus

Fig. 6: Chest X-ray of a neonate with infracardiac obstructed TAPVC. Note the normal sized heart with diffuse reticular infiltrates due to pulmonary edema

any lower limb or left upper limb (postductal) measured at baseline ($\text{FiO}_2=0.21$) and after 100 percent oxygen delivery (Table 4 for interpretation). PaO_2 more than 250 mm Hg in an arterial sample from right arm after 100 percent oxygen for 10 minutes excludes cyanotic congenital

Fig. 7: Chest X-ray in a neonate with pulmonary atresia and VSD. Note the boot shaped right ventricular apex, no cardiomegaly and pulmonary oligemia

heart disease, and if PaO_2 is more than 150, cyanotic heart disease is unlikely.¹⁰

Limitations of Hyperoxia Test

- Total anomalous pulmonary venous drainage (TAPVD) and hypoplastic left heart syndrome may respond to oxygenation.
- Pulmonary disease with a massive intrapulmonary shunt may not respond to oxygenation.
- This test is not as reliable as an echocardiogram and is not as important as resuscitation and attendance to cardiorespiratory support, especially if acidosis or respiratory distress is present
- Failed hyperoxia test will not differentiate cardiac disease from PPHN

All cyanotic lesions in the newborn should be considered as an emergency and pediatric cardiologist opinion should be sought as soon as possible. But critically ill newborns those are duct dependent will not give time and will need emergency administration of prostaglandin E1 infusion hence the need for every neonatal ICU to keep the prostaglandin in the emergency trolley (Table 5).

NO RESPONSE TO PROSTAGLANDIN INFUSION

If there is no response to prostaglandin infusion consider the following:

1. Noncardiac diagnosis.
2. Obstructed TAPVC.
3. TGA with Intact interventricular septum and restrictive PFO which needs emergency balloon atrial septostomy (BAS)

Table 4: Interpretation of hyperoxia test

	At $\text{FiO}_2 = 0.21$ PaO_2 (saturation %)	At $\text{FiO}_2 = 1.00$ PaO_2 (saturation %)	PaCO_2
Normal	>70 (>95)	>300 (100)	Normal
Pulmonary disease	50 (85)	>150 (100)	High
Neurological disease	50 (85)	>150 (100)	High
Methemoglobinemia	>70 (<85)	>200 (<85)	Normal
Cardiac disease	40-60 (75-93)	<150 (100)	Normal
PPHN	Preductal 40-70 (75-95) Postductal <40 (75)	Variable Variable	Normal

PPHN: Persistent pulmonary hypertension of newborn

Table 5: How do we start prostaglandin?

Dosage and administration

Prostaglandin is started at a dose of 0.001-0.4 microgram/kg/min infusion. Higher doses in the range of 0.1 microgram/kg/min should be used to reopen the closed PDA (or if there is sudden onset of severe cyanosis or shock). If prostaglandin fails to open the duct, the dosage should be increased in the increments of 0.05 microgram/kg/min every 5-10 minutes till 0.4 microgram/kg/min. Once the duct has opened, dose can be reduced to a minimum to keep the duct patent.

Lower doses in the range of 0.01 microgram/kg/min should be used once duct has opened and continued till definitive surgical repair. With proper monitoring in ICU for saturations and under echocardiographic guidance (for PDA monitoring), dose can be reduced to 0.001 microgram/kg/min.

Preparation

Prostaglandin is available at strength of 500 microgram per vial, dilute it in 50 ml of 5% dextrose and start in infusion pump.

According to formula (this formula can be used for any inotropes)

$3 \times \text{wt} \times \text{microgram/kg/min}$ divided by concentration (mg) in 50 ml = flow rate in ml/hr

So for wt of 3 kg child and dose of 0.1 mic/kg/min

$3 \times 3 \times 0.1/0.5 = \text{ml/hr}$ (0.9/0.5) = 1.8 ml per hr infusion will give you 0.1 microgram/kg/min prostaglandin in 3 kg child if you add 0.5 mg prostaglandin in 50 ml syringe.

The effect of prostaglandin usually is seen in half hour and infusion should be continued till the definitive diagnosis rules out duct dependent lesion.

enterocolitis). Bounding pulses in such cases along with wide pulse pressure should give a suspicion for the presence of hemodynamically significant PDA. One more common scenario in preterm PDA is after surfactant therapy, they show improvement and ventilatory requirements go down. As hyaline membrane disease improves and PVR falls, PDA shunt becomes significant and ventilatory requirements become higher. Other post-tricuspid lesions can also be seen in preterm neonates (e.g. large VSD, AP window) where they can present with CHF in early neonatal period. These post-tricuspid shunts usually don't present in full term neonates as PVR falls after 4 to 6 weeks and then shunt lesions start manifesting as CHF.

Among other acyanotic lesions with CHF are valvular regurgitant lesions like aortic regurgitation or pulmonary regurgitation (which may be secondary to vegetations of these valves also). Congenital mitral valve lesions with severe MR can also present in neonates with CHF. Diastolic murmur in AR or PR and pansystolic murmur in MR will give a significant clue. Chest X-ray in such cases will show Cardiomegaly of the respective chambers (cardiothoracic ratio >0.6). This is important to remember that thymic shadows and extracardiac shadows can lead to over diagnosis of cardiomegaly on chest X-ray (Figs 8 and 9).

Among cyanotic heart diseases which present in neonatal life with CHF are those with significant high pulmonary blood flow like truncus arteriosus or single ventricular physiology without pulmonary stenosis.¹¹ Important point to remember in such cases is that these neonates will not be significantly cyanotic due to torrential pulmonary blood flow and saturation may vary in the range of 90's, so naked eyes will not pick up the cyanosis and pulse oximetry will help in the early detection of such congenital lesions.

Asymptomatic Newborn with Murmur

This is a group where lesions are usually mild forms of obstructive or regurgitant lesions. These lesions can be aortic stenosis or pulmonary stenosis. These obstructive lesions are characterized by presence of harsh murmur

Neonate Presenting with Congestive Heart Failure

The early features of congestive heart failure in neonates will be difficulty in feeding, subcostal indrawing, sweating with feeds, tachypnea, tachycardia, gallop rhythm and hepatomegaly. Most common group would be preterm neonate with post tricuspid shunt lesion, mainly patent ductus arteriosus. Preterm with PDA can also present with steal phenomenon like cerebral steal (manifesting as apnea) or steal from gut (manifesting as necrotizing

Fig. 8: Chest X-ray (rotated film) of a normal neonate with large thymus appearing as cardiomegaly

Fig. 9: Chest X-ray showing left-sided space occupying lesion with dextroposition of heart mimicking cardiomegaly. Patient had cyanosis and respiratory distress at birth due to space occupying lesion in thorax

and click if obstruction at the valvar level. TOF with absent pulmonary valve will present with to and fro murmur which is very classically heart in left 2nd intercostal space. Ebstein with TR will present with PSM at tricuspid area and multiple ejection clicks will confirm the diagnosis. Classical forms of Ebstein anomaly will have box shaped heart on CXR. Severe forms of Ebstein anomaly will present with cyanosis due to lack of forward flow across pulmonary valve and may need prostaglandin infusion for pulmonary circulation. Mitral regurgitation may be seen in isolation or with atrioventricular canal defects with cleft mitral valve. These defects may present as asymptomatic or may present with CHF at 10 to 14 days of life with CHF if MR is severe.

Another group of neonates presenting with murmur will be left to right shunt (post-tricuspid) lesions which are restrictive (small or moderate shunts) and usually present with a murmur when PVR falls (after the age of 2 to 4 weeks). Few cases of small defects may present with murmur in first week also. This group of neonates are usually asymptomatic in the neonatal period due to restrictive nature of shunts and start having symptoms beyond the neonatal period. This is important to mention in such cases that preterm neonates may have symptoms within neonatal period as in preterm PDA cases.

Physiological peripheral pulmonary stenosis is a frequent finding in neonates and there may be a significant systolic murmur in such cases. Pediatric cardiologist must

take care not to miss cases of syndromes associated with peripheral stenosis like Alagille, congenital rubella syndrome and William's syndrome. Physiological peripheral pulmonary stenosis is reduced in two-thirds of cases by 6 weeks of age and in most others by 6 months. The etiology of the murmur is secondary to both relative hypoplasia of the pulmonary artery branches and an associated angulation at their origin.

This is important to understand that many duct dependent lesions in the immediate neonatal period may be totally asymptomatic till the PDA is open and minimal cyanosis or a murmur of PDA may be the only finding in such cases. These are the cases which may go undetected, discharged and later comeback in critical situation.¹² In such cases repeated and careful clinical examination, pulse oximetry along with chest X-ray and ECG are helpful to assess the severity of lesion.

SUMMARY

Neonates with cardiac disease may present in one of the four groups-shocks, cyanosis, CHF and asymptomatic. Differentiating from noncardiac causes is feasible on bed side examination along with pulse oximetry, chest X-ray, ECG and other basic investigations such as hyperoxia test.¹ Also not all murmurs are due to heart disease and not all newborns without a murmur are free of CHD. Prostaglandin E1 may be started empirically in shocky neonates and also in failed hyperoxia test which can be life saving.⁸

Critical congenital heart lesions in neonates have a better outcome if referred early for a surgical repair in today's world even in developing countries.

Diagnostic Cardiac Evaluation of a Neonate

Poonam Sachdev, Neeraj Agarwal, Manvinder Singh Sachdev

INTRODUCTION

Congenital heart diseases (CHDs) are considered important as they are a leading cause of morbidity and mortality in infancy.¹ According to studies the incidence of congenital heart defects is 7 to 8 per 1000 live-born infants and cause 3 percent of all infant deaths. The CHD are the commonest group of congenital anomalies which cause 46 percent of deaths attributable to congenital malformations. Many of the critical congenital heart diseases are recognized when the infant manifests life-threatening symptoms of cardiovascular collapse. A critical CHD can be defined as a congenital heart disease which requires surgery or catheter intervention in infancy. Early detection can prevent death or cardiovascular collapse with its attendant morbidity and improve the outcome of congenital heart defects.²

CLINICAL PRESENTATION

Congenital heart disease (CHD) may be diagnosed at any age from newborn period to adulthood. Many CHD's always present in the newborn period whereas others are rarely identified during infancy.³ Many studies indicate that of all the CHD 50 percent are detected by 1 month, 75 percent by 3 month of age and about 100 percent by 3 to 4 years of age.¹ The presentation of different CHD's varies with time owing to the variable rate of decrease or change in pulmonary vascular resistance (PVR) after birth and variation in the time interval for closure of ductus arteriosus.¹ The common presentations of neonates who need care of a pediatric cardiologist are:³

- Asymptomatic murmur
- Cyanosis (often without a murmur)
- Gradually progressing symptoms of heart failure or
- Catastrophic heart failure and shock.

These findings are not always evident before the newborn is discharged from the hospital at about 48 hours of life.¹ The latter two presentations mostly occur after

discharge from the hospital.³ Many newborns with critical congenital heart disease present with sudden significant deterioration of clinical status in the first few days or weeks of life and some may be so severely sick at presentation that they die before surgical intervention. Studies suggest that timely recognition of critical congenital heart disease could improve outcomes hence, it is important to have strategies that can help in timely diagnosis and treatment of these infants.^{1,3}

DIAGNOSIS

The evaluation and diagnosis of a newborn with congenital heart defect is challenging. The current objective of CHD diagnosis is presymptomatic identification of life-threatening congenital heart defects and other clinically significant congenital heart defects as timely recognition can improve outcomes. Strategies for timely identification of critical and clinically significant congenital heart defects include fetal echocardiography and physical examination within the first 24 hours of life and on subsequent nursery visits. Pulse oximetry, electrocardiograms, chest radiographs, echocardiograms are supplemental tests which are done in suspicious cases.⁴

Physical Examination

Cardiovascular system examination at the time of clinical newborn examination is considered to form part of newborn screening for congenital anomalies. The newborns are also examined at the subsequent nursery visit and again at 6 to 8 weeks of age. However, this strategy has not been effective in improving outcome for infants with congenital heart defects.²

Fetal Echocardiography

Prenatal ultrasound to detect fetal anomalies can advance the time of diagnosis of congenital anomalies from postnatal

to fetal life.⁵ The risk of death due to congenital heart disease before diagnosis has decreased with the increased application of fetal echocardiography and improved understanding of the presentation of critical congenital heart diseases (CCHDs). However, mortality due to CHD continues to remain significant.^{2, 4}

According to some studies short-term outcomes of CCHD has improved with prenatal diagnosis as compared to postnatal diagnosis.^{6,7} However, improved survival with prenatal diagnosis has not been observed in numerous other studies.^{8,9}

Fetal echocardiography for congenital heart anomalies is usually done at 18 to 20 weeks' gestation. A methodical scan can identify many cases of CHD if not all. If a CHD is identified or suspected during the scan the patient may be referred to a pediatric cardiologist for confirmatory imaging and counseling. With knowledge that the fetus has CCHD, arrangements for delivery of the newborn at a hospital with advanced medical facilities like a tertiary level neonatal intensive care unit where intensive care, prostaglandin infusion, mechanical ventilation, etc. are available can be made. After stabilization the newborn can be transferred to a center specializing in surgery and care of children with congenital heart disease.⁴

A methodical scan can identify many cases of CHD if not all when it is done by a health care professional with specific training in congenital heart disease. However according to many studies even when fetal ultrasound is regularly done during pregnancy, less than 50 percent of cases of CCHD are recognized as many scans may be done by professionals with inadequate training. Besides the concerns about the quality and low detection rate on anatomic ultrasounds limited access to prenatal ultrasound also remains a major problem.⁴ Even in developed countries like the United States, an anatomic ultrasound is not performed in all women.¹⁰ Therefore this methodology alone is not adequate to identify a high proportion of cases.⁴

PULSE OXIMETRY AND DETECTION OF CHD

Currently many investigators have suggested that pulse oximetry should be used along with newborn physical examination after delivery to enhance timely detection of CCHD.^{11,12} Pulse oximetry is an accepted modality of assessment of young children in neonatal intensive care units and in other emergencies.¹³

Hypoxemia is often present in many congenital heart diseases. It occurs due to mixing of systemic and venous circulations or parallel circulations as present in d-transposition of the great arteries. Hypoxemia may cause obvious central cyanosis but for this 4 to 5 g of deoxygenated hemoglobin should be present irrespective of total hemoglobin concentration. Hence, if a newborn has a hemoglobin concentration of 20 g/dL, cyanosis will

become evident when arterial oxygen saturation is <80 percent and in an infant with hemoglobin concentration of 10 g/dL, it will become obvious when the saturation is <60 percent. Cyanosis may not be obvious in children with mild hypoxemia that is if the arterial oxygen saturation about 80 to 95 percent. Besides this, identification of cyanosis can be difficult in dark skinned neonates and infants because of skin pigmentation. Majority of CCHD have some amount of hypoxemia in the newborn period.⁴

According to some experts pulse oximetry should be considered as a vital sign equivalent to pulse, respirations, and blood pressure during clinical examination.¹⁴ Centres where pulse oximetry is routinely used have noted that it has contributed to improved detection of congenital heart disease in neonates. Although some studies have observed improved detection rate with pulse oximetry the efficacy of oximetry in clinical practice for CCHD is not well established. There are some limitations of pulse oximetry in detection of CCHD. Pulse oximetry cannot identify all cases of CCHD, hence if the test result is negative possibility of a heart disease is not excluded. In addition oximetry screening is not very effective in identifying the CCHD lesions which are at greatest risk for acute cardiovascular compromise, namely, obstructive left heart lesions such as aortic stenosis, and coarctation of the aorta. Further studies are needed to establish the usefulness of pulse oximetry for detection of CHD and whether it should be considered as standard of care in the routine assessment of the neonate.⁴

Chest X-ray

Chest X-ray (CXR) may not be useful for detection of many of the CCHD lesions in the newborn period however it is still considered as an important modality of investigation for CHD. Several changes in the CXR due to congenital cardiovascular abnormalities have been described which are recognized to be clinically important. Whenever the CXR of a child is being reviewed consider the age of the patient, the posture (that is whether if the film was taken in the sitting or lying position) and evaluate the X-ray systematically.¹⁵

- *Check alignment and penetration:* The CXR is considered adequately penetrated if the disk spaces of the lower thoracic vertebrae are seen through the heart shadow. On the right hand side a minimum of 5 anterior rib ends should be visualized. To assess the alignment the medial ends of both clavicles is observed. They should be equally spaced about the spinous processes of the upper thoracic vertebrae.
- *Check bones, cartilage and soft tissues:* Observe the ribs, clavicles and vertebrae. Evaluate both the lung fields systematically and check for pleural effusions, pneumothorax, changes in vascular markings (increased or decreased that is plethoric or oligemic lung fields),

fluid in the fissures, consolidation or hemorrhage. Assess the cardiac size and the cardiothoracic ratio. In infants the normal heart can be up to 60 percent of the thoracic diameter, and later is about 50 percent of the thoracic diameter. However, a normal cardiac shadow does not exclude the possibility of cardiac disease. Interpreting Cardiac shadow in a neonate may be tricky because of thymus or expiratory film which may present as cardiomegaly in many cases (Fig. 1).

- *Check diaphragm:* Assess the cardiophrenic and costophrenic angles. Both should appear clear and well demarcated.
- Some of the well recognized appearances of heart disease on CXR are:¹⁶
- *'Egg-on-side':* Transposition of great arteries (Fig. 2)
- *Boot shaped heart:* Tetralogy of Fallot (lung fields appear oligemic) (Fig. 3)
- *'Snowman in a snowstorm':* Obstructed total anomalous pulmonary venous connection in a neonate (Fig. 4)
- *Globular heart:* Usually associated with pericardial effusions, dilated cardiomyopathy (Fig. 5)
- *Situs:* In the normal situation (situs solitus) the heart is on the left with the gastric bubble on the left and the liver on the right. In situs inversus these relations are reversed.
- *Oligemic lung fields:* Associated with cardiac conditions with reduced pulmonary blood flow such as TOF and pulmonary atresia (Fig. 3)
- *Plethoric lung:* Observed in cardiac conditions with increased pulmonary blood flow such as VSD and ASD (Fig. 6)

Fig. 7: ECG showing left axis deviation, LVH, No right ventricular forces in a 6-week-old with tricuspid atresia, restrictive VSD, pulmonary stenosis (on treatment with β -blocker)

Electrocardiogram (ECG)

The ECG may be useful to investigate rhythm and conduction abnormalities, as well as assessing chamber hypertrophy and strain. The use of ECG in neonates for a guide of diagnosis is considerably limited in view of Right ventricular preponderance in a neonate and most cyanotic neonates too have right ventricular dominance as their ECG findings. Nevertheless ECG may be helpful in certain conditions as below.

- Left axis deviation with left ventricular dominance in a neonate with tricuspid atresia (Fig. 7)
- Superior axis in patients with endocardial cushion defects
- Neonates with abnormality of rhythm (Bradyarrhythmia or tachyarrhythmia) (Fig. 8)

ECG alone may not be useful but when used in conjunction with chest X-ray findings it may help to narrow down the differentials in patients presenting with heart failure (Table 1).

Fig. 8: ECG showing a 2:1 AV block and long QT syndrome in a 2-day-old neonate presenting in bradycardia, QTc was measured to be 490 msec

Table 1: Differential diagnosis of heart failure using CXR and ECG			
ECG	CXR		
	Increased pulmonary blood flow	Pulmonary venous congestion	Decreased pulmonary blood flow
RVH	HLHS CoA Aortic stenosis Interrupted arch truncus arteriosus TAPVC (unobstructed) PDA AVSD ASD	TAPVC (obstructed) Mitral stenosis all with severe heart failure	Pulmonary stenosis Ebstein's anomaly
LVH	PDA Truncus arteriosus aortic stenosis Univentricular connection with unobstructed PBF	Aortic stenosis all with severe heart failure	PAIVS PS hypoplastic RV
BVH	VSD AVSD Truncus arteriosus DORV Univentricular connection with unobstructed PBF	all with severe heart failure	Complex forms of pulmonary atresia

(HLHS: Hypoplastic left heart syndrome; CoA: Coarctation of aorta; AVSD: Atrioventricular septal defect; TAPVC: Total anomalous pulmonary venous connection; DORV: Double outlet right ventricle, PDA: Patent ductus arteriosus; ASD: Atrial septal defect; VSD: Ventricular septal defect; PAIVS: Pulmonary atresia with intact ventricular septum)

ECHOCARDIOGRAPHY

Echocardiography is currently the most commonly used diagnostic modality postnatally for diagnosis and assessment of cardiovascular function in newborns with suspected congenital heart defects. The major advantage of echocardiography is the fact that it is an accurate noninvasive investigation in a newborn which gives both structural and hemodynamic status of congenital heart disease.¹⁷

INDICATIONS FOR ECHOCARDIOGRAPHY IN A NEONATE

- Any neonate presenting in heart failure
- Any neonate presenting in cyanosis or saturation less than 94 percent on routine exam
- Any neonate with a heart murmur
- Any neonate detected to have discrepancy in pulses
- Any neonate with abnormal blood pressure
- Cardiomegaly detected on a chest X-ray
- Neonate with unexplained hemodynamic instability.

An echocardiogram done for the above indications by a pediatric cardiologist or an experienced. Pediatric cardiac sonographer results in pickup of most congenital heart disease.

In a study Rice and her colleagues¹⁸ evaluated the effect of echocardiography in the management of newborns suspected of having congenital heart disease. The results of this study observed that echocardiography improved the management of sick newborns with no increase in morbidity and was accurate when compared to invasive diagnostic modalities such as cardiac catheterization. Leung et al.¹⁹ found that echocardiography had a sensitivity and specificity of 95.5 and 98.6 percent respectively in a study while evaluating 536 cardiovascular anomalies in newborns. The authors concluded that infants could be

correctly managed without cardiac catheterization and several other studies have corroborated these findings.¹⁹

A segmental approach needs to be followed for an accurate diagnosis of congenital heart disease in a neonate by echocardiography. This approach includes sequential analysis of situs, systemic and pulmonary venous drainage, atrioventricular and ventriculoarterial connections, looping of ventricles and associated intracardiac structures and assessment of great arteries their branches and ductus arteriosus. Also important consideration needs to be given to dimensions of the cardiac structures as well as hemodynamic information (measurement of gradients across the valves and pulmonary artery pressure assessment). Following this systematic approach ensures that the diagnoses reached properly explains the presentation as well as the hemodynamics.

With improving access to technology a functional echocardiogram done by a trained neonatologist in suspicious cases helps in pickup of congenital heart disease in a neonate even before they become critical. These will need to be confirmed by a pediatric cardiologist. Certain indicators on echocardiograms in a neonate with cyanosis are illustrated in Table 2. These findings on a functional echocardiogram should arouse considerable doubt leading to swift involvement of pediatric cardiologist and timely pick up and management of critical congenital heart disease.

Echocardiography in hands of a pediatric cardiologist is useful in diagnosing cyanotic congenital heart disease which clinically present as persistent fetal circulation and shows evidence of ventricular dysfunction, dilated right ventricle and presence of tricuspid insufficiency as identified on functional echocardiogram. Echocardiographic features which may help reach the diagnoses in such patients are indicated in the Table 2.

Table 2: Differential diagnosis of a sick newborn presenting with cyanosis

<i>Anomaly</i>	<i>Characteristic echocardiographic findings</i>	<i>Definitive echocardiographic features</i>
Total anomalous pulmonary venous drainage	Dilated right ventricle, small left atrium (bald appearance), interatrial septum bowing into the left, right-to-left atrial shunting	Right-to-left shunting across the interatrial septum
Functional pulmonary valve atresia	Dysplasia of tricuspid valve or Ebstein's anomaly, severe tricuspid insufficiency, dilated right atrium, no or minimal ante grade flow across the pulmonary valve, presence of pulmonary regurgitation	Presence of pulmonary regurgitation
Simple transposition of great arteries	Aorta from right ventricle, pulmonary artery from left ventricle; parallel great arteries, ductus arteriosus easier to visualize in the arch view compared to the parasternal short axis view	Bifurcating great artery arising from the left ventricle
Ebstein's anomaly of the tricuspid valve	Dilated right atrium, small right ventricle, apical displacement of the tricuspid valve attachment, tricuspid insufficiency	A very large right atrium and morphology of tricuspid valve
Dilated cardiomyopathy or myocarditis	Dilatation of the left ventricle with global hypokinesia, presence of mitral and tricuspid regurgitation	Rule out arch anomalies and coronary abnormalities

CONCLUSION

Timely identification of neonate with congenital heart disease especially those who are symptomatic is of paramount importance as when picked up on time and managed the results may be quite good. Institution of appropriate management can really help in improving the long-term survival of newborn with congenital heart disease. High index of suspicion, proper physical examination, institution of protocols in nursery which include blood pressure measurement and pulse oxymetry, use of chest X-ray, ECG and reliable echocardiogram by a pediatric cardiologist help in diagnosis and management of critical congenital heart disease in a neonate.

Screening for Inborn Errors of Metabolism

Sunita Bijarnia, Ratna D Puri, JC Verma

Abstract

Inborn errors of metabolisms (IEMs) are inherited disorders occurring due to block(s) in one or more biochemical pathways in human body. The IEMs are rapidly gaining importance in our country for reasons: (i) IEMs are collectively not uncommon in our country in view of the vast population and prevalence of consanguinity, and (ii) technological revolution and medical advancements leading to reduction in mortality due to infections and perinatal events. The awareness for these disorders is also essential as early detection has potential for treatment, thus prevention of death and irreparable brain damage. This article describes an approach for testing a sick neonate, as well as newborn screening. Diagnostic algorithms for a suspected case of IEMs are given. For newborn screening, the evolving methods are discussed including tandem mass spectrometry.

INTRODUCTION

Inborn errors of metabolism (IEMs) are genetic disorders occurring due to deficiency of an enzyme or co-factor or transporter in any metabolic cascade in our body.¹ This disrupts a biochemical pathway, leading to symptoms and signs due to accumulation of toxic metabolites prior to the block or deficiency of the end product beyond the metabolic block.

Nearly all the inborn errors of metabolism are inherited recessively, mostly autosomal and some X-linked. They are individually rare but collectively numerous.² They are increasingly being recognized because of the advancement in diagnostic facilities like blood gas analysis and automated biochemical tests, coupled with the reduction in mortality related to infections and perinatal asphyxia.³ Other factors that lead to an increased frequency of IEMs in our country are a huge population, high birth rate, and custom of consanguineous marriages among many communities.⁴ Limited studies have been published on the prevalence of IEMs in India.⁵⁻⁸ Nagaraja and Christopher et al reported a prevalence of 3.2 percent with a small molecule disorder (amino acidopathy, organic aciduria, and fatty acid oxidation defect) among a high-risk cohort in South India. At Sir Ganga Ram Hospital, a study of 393 cases suspected to have inborn errors of metabolism resulted in specific diagnosis in 56 (6.7%) cases (Table 1) (personal communication). At our center, we found a wide

range of metabolic disorders through similar screening, and the common disorders prevalent in our cohort were Methyl malonic aciduria, maple syrup urine disease and Citrullinemia type 1.

SCREENING FOR IEMS IN THE NEWBORN

Inborn errors of metabolisms can be broadly categorized into three groups.⁹ The enzyme defects occurring in the

Table 1: IEM: detected in a cohort of patient at Ganga Ram Hospital

Disorders detected	Number of children
Organic acidemias	38
Methyl malonic acidemia	12
Multiple carboxylase deficiency	8
Maple syrup urine disease (MSUD)	7
Glutaric aciduria type II	4
Propionic acidemia	3
3 methylglutaconic aciduria	2
Beta-ketothiolase deficiency	2
Urea cycle disorders	9
Citrullinemia	4
Argininosuccinic aciduria	2
Arginase deficiency	1
Ornithine transcarbamylase deficiency	1
HHH syndrome	1
Other disorders including Tyrosinemia 2	9

metabolism of amino acids, carbohydrates and fatty acids or in the mitochondrial energy metabolism are referred to as 'small molecule disorders'. Clinical manifestations of these disorders are severe and non-specific and occur early in life. In contrast, larger molecule or storage disorders, the symptoms develop gradually due to accumulation of substrates, thus resulting in progressive organomegaly and coarse body features. A third group is that of other miscellaneous disorders of metals (Wilson and Menkes disease), lipoproteins, congenital adrenal hyperplasia and hyperinsulinism.

The focus of this article is on the 'small molecule disorders' which comprise classical IEMs in the neonatal period. These disorders are dynamic, fluctuating with the patient's metabolic state and require early diagnosis for therapeutic intervention to prevent the irreparable brain damage.

APPROACH TO INBORN ERRORS OF METABOLISM

There are two approaches to screening for inborn errors of metabolism. The first is the testing of suspected cases in order to establish diagnosis in a sick neonate or infant. The second approach is to screen all newborns for selected group of disorders. This approach is ideal and an established practice in the developed countries as the babies who are screened positive for a known metabolic disorder then gets preventive treatment and develops normally with no or minimal disability in life. Mass newborn screening however requires huge investments and funding for ongoing expenses of the program. The newborn screening would only be considered successful if appropriate preventative strategies are available to the general citizens, which depend on the cost and effort from the government. Thus, it has yet to take off in India, although pilot studies have been started.¹⁰ Facilities for diagnosis of all IEMs to be included in newborn screening programs are now available in India (at least in the private sector) but the treatment possibility still eludes the average Indian in view of the overpowering costs and difficulty in procuring the special diets and medications. Once these facilities are set up and strong socioeconomic and health infrastructure has been built up, newborn screening should be initiated. Until that time, in our country, screening for high-risk neonate and infants seems the way to go.

SCREENING OF HIGH-RISK (SICK) NEONATES

Enormous strides have been made in the past three decades in the recognition and understanding of metabolic illnesses. The newborn appears to have a limited repertoire of ways to respond to insult, with the result that the clinical features of many inherited metabolic diseases are superficially indistinguishable from that of the commoner acquired conditions, such as infections and intoxications. Moreover, a newborn with an IEM may present

with a proven infection. Thus, a high index of suspicion is required in order to identify the sick neonate with an IEM. The diagnosis of IEMs should be considered along with that of other common illnesses, and should not be a diagnosis of exclusion. This would save the time which is of utmost importance for improving outcomes in these babies.

Pointers to the presence of IEM are:¹⁰

- History of acute deterioration after a period of normalcy after birth. This is so because symptoms are caused by postnatal accumulation of toxic metabolites, which were getting cleared *in utero* by the placenta and maternal metabolism. Examples are urea cycle defects, organic aciduria and galactosemia. However, it is important to note that this period of normalcy may not be always present and obscured by other problems like perinatal asphyxia.
- A family history of consanguinity or similar illness in a sibling.
- Progressive illness showing nonspecific signs of cerebral dysfunction such as poor sucking, limpness, vomiting, irritability, respiratory distress, lip smacking movements and hypothermia.
- Unusual odors may offer an invaluable aid to the diagnosis. In Maple syrup urine disease (MSUD), there is a characteristic odor of maple syrup or burnt sugar. Performing a DNPH test in the urine of such a case can make the diagnosis fairly easily.
- Some IEM are associated with concomitant sepsis and neutropenia like organic aciduria and galactosemia (*E. coli* sepsis).

Initial laboratory investigations (Table 2) should be carried out as soon as possible. Some tests like blood ammonia and lactate are considered crucial for diagnosis of IEMs and thus should be available to every neonatal care unit. Specialized investigations are performed depending upon the clinical features and initial investigations MRI brain is an important modality for diagnosis of some IEMs such as molybdenum cofactor defects, non-ketotic hyperglycinemias, pyridoxine dependent seizures etc, where there may be structural changes in the brain suggestive of the diagnosis.

A simplified algorithm for diagnosis of inborn errors of metabolism in an acutely sick neonate is given in Flow chart 1.

- Metabolic acidosis is an important finding and narrows down the diagnosis to a few disorders including all the organic acidurias and primary lactic acidurias. A diagnostic algorithm is given in Flow chart 2. The common organic acidurias prevalent in our country are methyl malonic aciduria, propionic aciduria, glutaric acidurias, multiple carboxylase deficiency and MSUD.⁸
- Hyperammonemia is a very useful clue, and often associated with encephalopathy and seizures. Urea

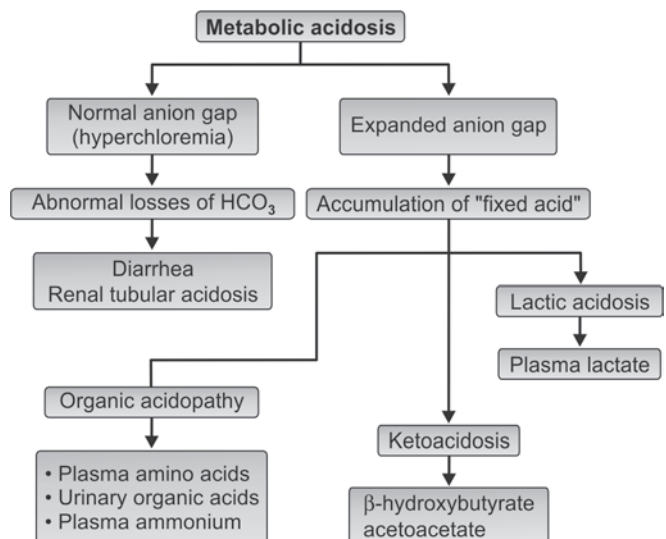

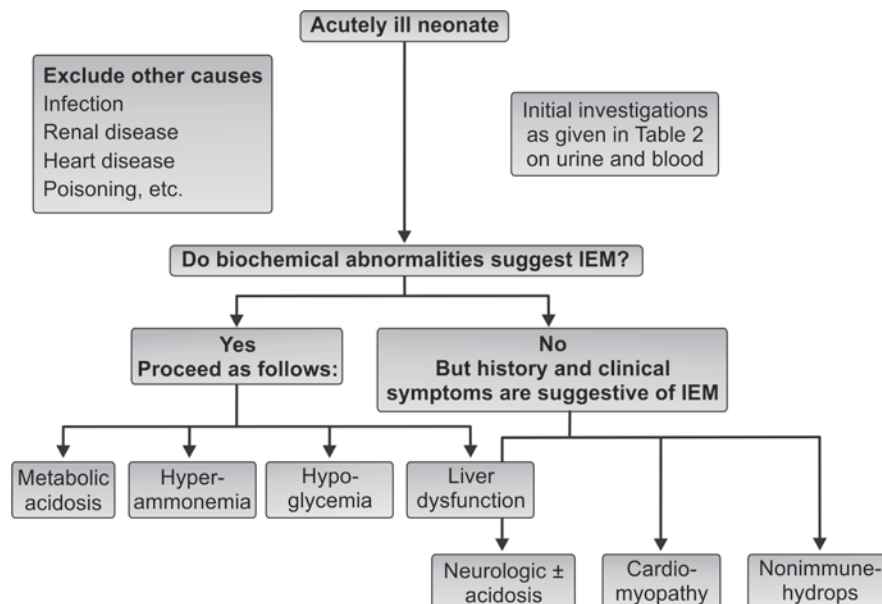

Table 2: Investigations in a suspected case of IEM

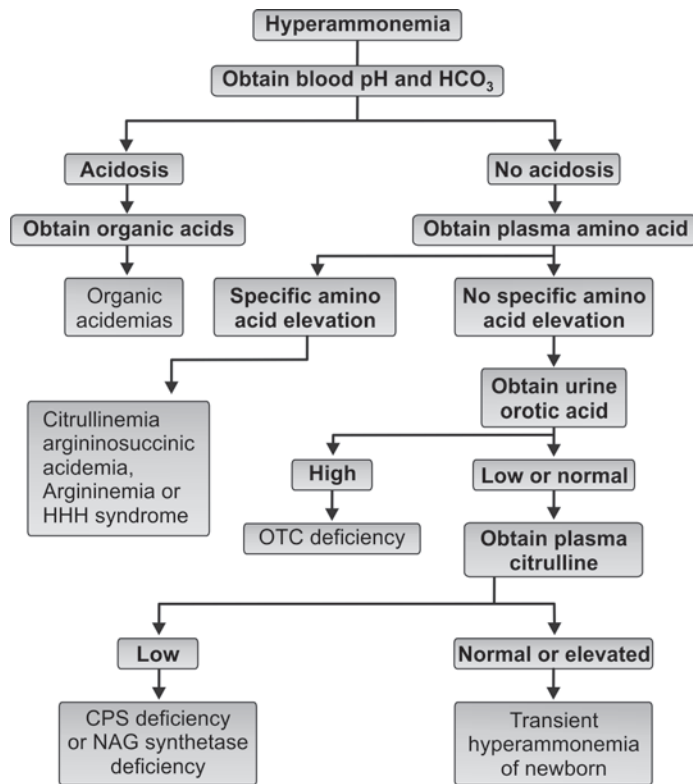

A. Initial investigations	Blood: Hemoglobin, white blood count, platelets Blood gases and plasma electrolytes (anion gap $(\text{Na}^+\text{K}) - (\text{HCO}_3^- + \text{Cl}) =$ normal <20 mmol/L) Glucose Calcium, magnesium Blood urea nitrogen, creatinine Liver function tests (Prothrombin time, liver enzymes, albumin, etc.) Ammonia Lactate Urine: Specific gravity, pH Proteins Sugar, reducing substances (Benedict's and uristix) Ketones, ketoacids (DNPH) Sulfites Microscopy
B. Specialized investigations	Blood: Amino acid analysis, quantitative Galactosemia screening test Carnitine, total and free (Tandem Mass Spectrometry) Plasma for storage at -200°C : 2-5 ml Urine: Organic acids (GC-MS) Succinylacetone Urine for storage at -200°C : 10-20 ml Neuroimaging: CT/MRI brain

Modified from Clarke JTR¹¹

cycle disorders usually occur without metabolic acidosis. These babies require immediate treatment with sodium benzoate or phenyl butyrate if available as delay in initiation is directly related to adverse outcome. Raised ammonia in presence of metabolic acidosis suggests organic aciduria, which can be diagnosed using the approach given in Flow chart 3. Other causes of raised ammonia are lysinuric protein intolerance, liver failure and 'congenital hyperinsulinism with hyperammonemia'.

- Blood glucose is a universal investigation performed on all sick neonates and thus hypoglycemia is commonly encountered. When common causes of hypoglycemia like maternal diabetes, small for gestational

Flow chart 2: Diagnosis of metabolic acidosis**Flow Chart 1:** Diagnosis of IEM

Flow chart 3: Diagnosis of hyperammonemia

age baby and sepsis are ruled out, one can follow the algorithm given in Flow chart 4 to make a diagnosis of IEM. It is a good practice to check urinary ketones in all babies at the time of hypoglycemia.

- Neurologic dysfunction occurs most commonly in newborn in form of lethargy, poor reflexes and seizures. This encephalopathy may or may not be associated with acidosis. While the disorders related to acidosis are given above, the IEMs associated with encephalopathy without acidosis include:
 - Urea cycle disorders
 - Maple syrup urine disease
 - Homocystinuria
 - Pyridoxine dependent seizures
 - Xanthine-sulfite oxidase deficiency/molybdenum cofactor defects
 - Nonketotic hyperglycinemia
 - Electron transport chain disorder or Pyruvate dehydrogenase deficiency
 - Fatty acid oxidation defects
 - Peroxisomal disorders like Zellweger syndrome
- Hepatic involvement manifesting as jaundice, hepatocellular dysfunction and hypoglycemia, is a common presentation of many inborn errors of metabolism. The main disorders here are amino acidopathies—hepatorenal tyrosinemia, disorders of carbohydrate metabolism—hereditary fructose intolerance (HFI)

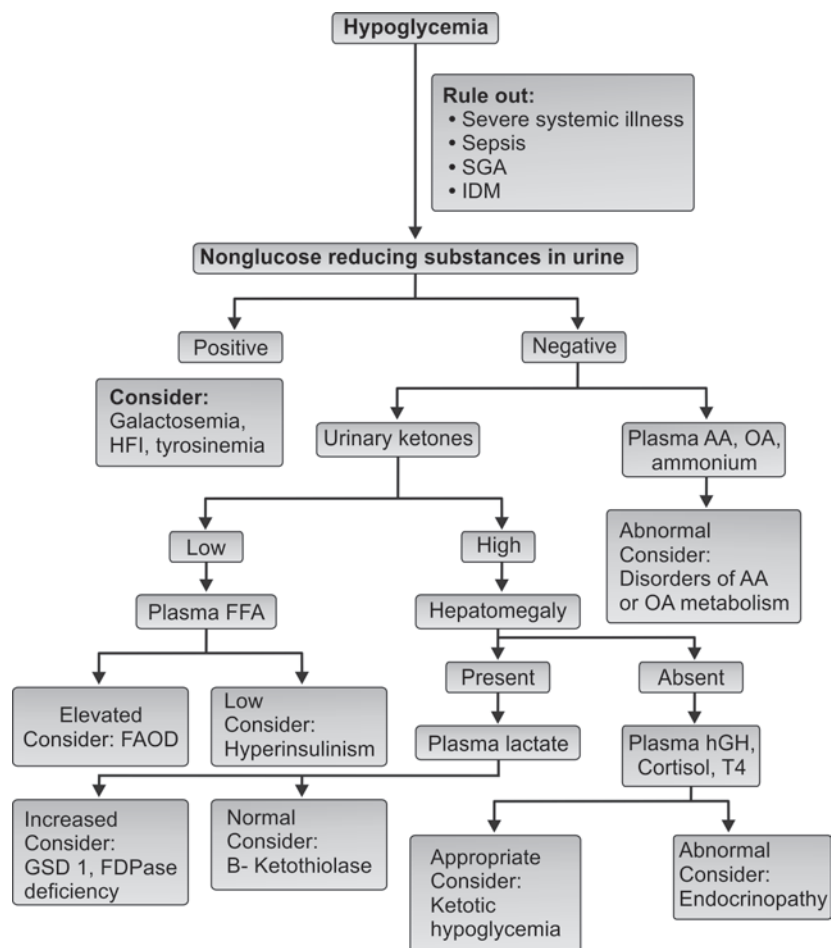

and glycogen storage diseases (GSD), fatty acid oxidation defects—Medium chain acyl CoA dehydrogenase (MCAD), long chain acyl-CoA dehydrogenase (LCAD), carnitine palmitoyl transferase II deficiency (CPT II) and carnitine–acylcarnitine translocase deficiency (CAT).¹⁰ These disorders are diagnosed by tandem mass spectrometry. Mitochondrial energy metabolism—cytochrome C oxidase deficiency and mitochondrial depletion syndromes also present with hepatic symptoms.

- Nonimmune hydrops may be due to IEMs and these should be suspected after exclusion of anemia and hemolysis and in the presence of significant organomegaly. Main IEMs to be looked for are GM1 Gangliosidosis, Gaucher Disease, Niemann-Pick disease, Sialidosis, Galactosialidosis, I-cell disease, Morquio (MPS IV) and Sly disease (MPS VII).
- Cardiac involvement occurs as rhythm disturbances, shock like symptoms, cardiomegaly or cardiomyopathy leading to cardiac failure.² Some IEMs such as glycogen storage disease type 2, fatty acid oxidation defects – MCADD, VLCADD, CPT I and II deficiency, primary carnitine deficiency, tyrosinemia type 1 and mitochondrial electron transport chain disorders may present with cardiac symptoms.

COLLECTION, STORAGE AND TRANSPORT OF SAMPLES

- Urine:** Collect 10 to 15 ml of urine, preferably first morning specimen (sufficiently concentrated). Tests include:
 - Routine biochemical tests, protein, glucose, reducing substances, pH
 - Chemical tests like DNPH, ferric chloride test, Sulfite dipstick test, etc.
 - Amino acid chromatography and quantitative estimation
 - Organic acids (collect on filter paper).
- Blood**
 - For ammonia estimation, a free flowing fresh sample should be drawn in vial and transported directly to lab on ice as soon as possible. This is critical, as ammonia tends to rise falsely if sample is not processed immediately. For lactate and pyruvate, a fluoride vial is used and same precautions as for ammonia are to be taken.
 - Collect in EDTA if plasma is required for testing or for storage.
 - For galactosemia and tyrosinemia testing, heparinised blood is required.
 - For enzyme assays on blood leukocytes, blood sample should be collected in EDTA vial.
 - For tandem mass spectrometry, take fresh blood on filter paper; or 1 ml of blood in heparin or EDTA vial and put on filter paper.

Flow chart 4: Diagnosis of hypoglycemia

Every suspect case of IEM who is very sick should have following samples stored for diagnostic purpose and to carry out prenatal diagnosis in the family's future pregnancies.

- DNA - collect blood in EDTA tube. All gene studies require DNA sample. DNA to be stored at 4 to 8 degree Celsius.
 - Plasma to be stored at –20 degrees Celsius.
 - Urine to be also stored at –20 degrees Celsius.
 - Other body tissues—CSF, liver, muscle, bone biopsy, kidney etc. may be utilized later for diagnostic purpose and therefore should be stored in culture medium for enzyme assays and DNA studies.
- Transport of samples on filter paper (blood spots and urine) and DNA can be done in room air while plasma samples and blood for enzyme assays need to be cooled during transportation.

THERAPY, GENETIC COUNSELING AND PRENATAL DIAGNOSIS

Management of inborn errors of metabolism is out of scope of this article. Books on IEM may be consulted.^{1,2, 9,11,12}

It is essential to make a diagnosis in a given suspected case of IEM for genetic counseling and prenatal diagnosis in the couple's subsequent pregnancies. This holds importance in our country since the burden of these disorders is high in view of the enormous cost of treatment, difficulty in procuring the drugs/diets from abroad and lack of government funding or initiative. Blood and urine sample should be stored in anticipation of an adverse outcome as the diagnosis can be made on these samples later.

Prenatal diagnosis can be offered after an accurate diagnosis by DNA technology or enzyme assay on chorionic villi or cultured amniocytes, as there is a 25 percent risk of recurrence in all the autosomal and X-linked recessive disorders.

NEWBORN SCREENING FOR INBORN ERRORS OF METABOLISM

A novel idea struck Robert Guthrie in 1961 and the world of the newborn transformed like never before. He successfully performed a test on dried blood spots on filter paper for phenylketonuria.¹³ Medical science took a major leap forward and newborn screening emerged as a preventive

health program to prevent mental retardation. Newborn screening is mandatory in many developed countries as part of their public health programs. The time has come to introduce newborn screening programs in India.

WHO task force committee defines newborn screening as a “public health program aimed at the early identification of conditions for which early and timely interventions can lead to the elimination or reduction of associated mortality, morbidity and disabilities.¹⁴ It involves the following components: screening, short-term follow-up, diagnosis, treatment/management, and evaluation”.¹⁵ Thus, it is not just diagnosis but also about treatment to prevent disabilities and reduce the burden of such illnesses. Neonatal screening service involves many professionals such as nurses, laboratory technicians, clinical biochemists, pediatricians, neuropsychiatrists, social workers, obstetricians, medical geneticists but some one is required to coordinate all these activities.

Since the introduction of screening for phenylketonuria, many other disorders have been added for analysis of dried blood spots on filter paper. Newborn screening for congenital hypothyroidism was introduced in 1974 by Dussault et al.¹⁶ Newborn screening for CH has been dealt with elsewhere in the book. The early 90s saw another sea-change in the newborn screening with advent of TMS (tandem mass spectrometry) for detection of many other in-born errors of metabolism. This was different as it changed the paradigm of one test–one disease. Presently as many as 30 disorders amongst the 600 odd IEMs are detectable in one test using the filter paper methodology.¹⁷ Advances have been made further in the new millennium with LC-MS/MS technology being incorporated—providing extra sensitivity to the assays.

PRINCIPLES AND CRITERIA FOR NEWBORN SCREENING

Screening is the application of a test to people who are as yet asymptomatic, with the purpose of classifying them with respect to their likelihood of having a particular disease. Since the tests are carried out on normal individuals, this raises certain ethical issues. The WHO (1968) had outlined certain criteria for a screening program based on principles formulated by Wilson and Junger.¹⁸ These are:

- Clinically and biochemically well-defined disorder
- Known incidence in the population
- Disorder associated with significant morbidity or mortality
- Effective treatment available
- Period before onset during which interventions improves outcome
- Ethical, safe, simple and robust screening test
- Cost-effectiveness of screening is established

Newborn Screening Methodology

The newborn screening methods have evolved over the last 4 decades from the basic bacterial inhibition assay used for phenylketonuria by Robert Guthrie to the more sophisticated tandem mass spectrometry today. Methods such as ELISA and time resolved fluorometry are being used in many countries for newborn screening because of its low cost and rapid analysis of multiple samples. Conditions included in Newborn screening programs are given in Table 3:¹⁴

The various analytes tested for screening of above disorders and the evolving methodologies from time-to-time are enlisted in the Figure 1.¹⁴

Tandem Mass Spectrometry (TMS or MS/MS)

Tandem mass spectrometry is an established method for newborn screening in the developed world in view of its simplicity, rapidity and ability to detect a number of disorders in the one sample. It has its own controversies as it has the ability to screen some disorders also which do not have any treatment at present.¹⁹

Tandem mass spectrometry expands neonatal screening to several disorders in amino acid, fatty acid oxidation and organic acid metabolism, more than 60 in number. TMS can improve the detection of PKU also. A high sensitivity (95.4%) and specificity (99.7%) is reported with a

Table 3: Conditions included in newborn screening program

Common disorders

Phenylketonuria
Endocrine
 Congenital hypothyroidism
 Congenital adrenal hyperplasia (21 hydroxylase deficiency)
G-6-phosphate dehydrogenase deficiency
Galactosemia
MSUD
Biotinidase deficiency
Homocystinuria
Tyrosinemia
Cystic fibrosis
MCAD
Alpha-1 antitrypsin deficiency

Other disorders

Infections
 HIV
 Toxoplasmosis
Tumors
 Neuroblastoma
Ambiental toxicity
 Lead exposure
Sickle cell anemia
DMD
Hypercholesterolemia

combined prevalence of 1:2336 (in Germany).²⁰ Treacy et al argue that after diagnosis using TMS, response to treatment was complete in 12 percent of IEMs, there was no response in 34 percent, and in more than half (54%) there was a partial response, which justifies some intervention.²¹ Another study from Australia showed the benefit of newborn screening in improving outcomes in children with Glutaric aciduria type 1.²² Thus, TMS provides an early diagnosis and facilitates early intervention, so that 'partial benefits' can become 'substantial benefits'. Further, once an IEM is diagnosed in a family, a prenatal diagnosis can be performed to prevent birth of a child if it is a disorder which is not treatable. This perhaps has more relevance in our country with little resources and health care system not being completely state funded.

Indian Scenario

India has progressed immensely in the field of medical technology and health care. Therefore, this is the time to implement a newborn-screening program. Pilot studies conducted hope to give us the exact prevalence of the IEMs in different parts of the country before starting a national program. While the world is moving on to better technologies such as LC-MS/MS or even DNA based screening for newborns (for cystic fibrosis, etc.),²³ India is at a stand still and has a long way to go.

CONCLUSION

It is the fundamental right of a human being to live a disease free life as far as possible. The newborn screening systems can help in achieving this goal. Let us benefit from the medical advancements and give our newborns a disease free life.

CHAPTER 33

Retinopathy of Prematurity

Amit Khosla, Neeraj Manchanda, Tinku Bali

INTRODUCTION

Retinopathy of prematurity (ROP) has been recognized as an important cause of childhood blindness. It is a retinal vasculopathy that occurs almost exclusively in preterm infants. An arrest in the development of retinal vessels, triggered by extreme prematurity, sets off a cascade of molecular events which may cause mild, usually transient changes of the peripheral retina to severe progressive vasoproliferation, scarring, and potentially blinding retinal detachment. Retinopathy of prematurity (ROP) refers to all stages of the disease and its sequel.

PATHOGENESIS

Retinopathy of prematurity is a condition confined to the immature retinal vascular system. The likelihood of developing retinopathy is related to the degree of vascular development so that once the retina is fully vascularized, the risk of developing ROP has passed.

Vascularizing proceeds centrifugally from the optic disk, commencing at about 16 weeks of fetal life and is complete in the nasal retina by 32 weeks gestation age (GA) and by about 37 to 40 weeks GA in the temporal retina. Thus, as retinal vascularization proceeds symmetrically from the optic disk to the ora serrata, there is an advancing circumferential border between vascular and avascular retina. It is within this border area that acute ROP develops. This predictable pattern of retinal vascularization was formally recognized by ICROP (International Classification of Retinopathy of Prematurity), which divided the retina into progressive concentric zones. The location of ROP is described in terms of these arbitrarily defined zones. The appearance of the disease at a rather consistent postmenstrual age (PMA), regardless of the elapsed time following preterm birth or subsequent neonatal events, suggests that the innate maturation process

of the retina and its vessels is related to the timing of this disorder's onset and progression.

Both vascular endothelial growth factor (VEGF) and insulin-like growth factor (IGF-1) are implicated in normal vascular development and ROP pathogenesis. A better understanding of the vascular development is an area of current investigation.

RISK FACTORS

Risk factors of ROP include measures of immaturity (low-birth weight and low gestational age), metabolic acidosis and sepsis. Systemic steroids administered to the mother prior to preterm delivery have been shown to reduce the risk of ROP. Surfactants do not significantly alter the proportion of babies at risk who develop severe ROP and the role of systemic vitamin E is controversial. Clinical trials of reduced light exposure in the nursery have shown that this intervention has no impact on the incidence of ROP. The role of genetic factors remains unclear. Norrie disease gene mutations have been found in some infants with ROP, but the significance of this is still to be determined and ethnic factors may have some implications in ROP development.

CLASSIFICATION

The currently used International Classification of ROP (ICROP) describes the location, extent, and severity of the disease.

Location

To delineate location, the retina is divided into three concentric zones, centered on the optic disk (Fig. 1). Zone I, the posterior or inner zone, extends twice the disk-macular distance in all directions from the optic disk. Zone II, the middle zone, extends from the outer edge of zone I to the ora serrata nasally and to the anatomic equator

Fig. 1: ROP zones as described in the ICROP classification

temporally. Zone III, the outer zone, is the residual crescent that extends from the outer border of zone II to the ora serrata temporally.

As retinal blood vessels grow progressively across zone 1 through zone 3, the location of normal vascularization or ROP broadly reflects maturity and the progress of retinovascular development. Thus, the extremely immature baby whose retinal blood vessels are still within zone 1 at initial screening is at the greatest risk of the most severe disease. For instance, incomplete vascularization in zone I carries a 54 percent risk of reaching threshold ROP while for zone II this is only 8 percent. The larger baby whose retinal vessels have already grown into zone 3 by the initial exam has an extremely low risk of developing severe ROP, and when it does occur, it is likely to be mild, with a close to zero risk of visual impairment.

Extent

The extent of involvement is described by the number of circumferential clock hours involved.

Stages

The phases and severity of the disease process are classified into five stages:

Stage 1: It is characterized by a demarcation line that separates vascularized from avascular retina. This line lies within the plane of the retina and appears relatively flat and white (Fig. 2).

Stage 2: It is characterized by a ridge; the demarcation line has grown, acquiring height, width, and volume, and extending up and out of the plane of the retina. It may change from white to pink. Vessels may leave the plane of the retina to enter the ridge (Fig. 3).

Stage 3: It is characterized by the presence of a ridge and by the development of extraretinal fibrovascular tissue (Fig. 4).

Stage 4: It has subtotal retinal detachment caused by traction from the proliferating tissue in the vitreous or on the retina. This is subdivided into two phases:

Fig. 2: Stage 1 ROP showing demarcation line
(For color version see plate 2)

Fig. 3: Stage 2 ROP showing a ridge (R)
(For color version see plate 3)

Fig. 4: Stage 3 ROP showing extraretinal fibrovascular proliferation
(For color version see plate 3)

Fig. 5: Plus disease with dilatation and tortuosity of vessels at the posterior pole (*For color version see plate 3*)

- Subtotal retinal detachment not involving the macula (Fig. 5)
- Subtotal retinal detachment involving the macula.

Stage 5: It is total retinal detachment.

Stages 1 and 2 are referred to as mild ROP as they often resolve without visually threatening ophthalmic sequel. Stage 3 ROP is the first ROP stage that presents a significant risk of poor structural or visual outcome and thus represents serious disease. Stage 4 and especially Stage 5 usually result in some permanent visual impairment despite surgical intervention.

Plus Disease

When signs of posterior retinal vascular changes accompany the active stages of ROP, the term *plus* disease is used, characterized by the dilatation and tortuosity of the retinal vessels (Fig. 6) frequently along with the engorgement of the iris vessels, pupillary rigidity and vitreous haze. It is a critical sign of severe ROP and its presence is an important prognostic indicator.

Threshold disease is stage 3 ROP in zone I or II in 5 or more contiguous clock hours or 8 cumulative clock hours [30° sectors] with plus disease. This represented the minimum severity of disease indicating the need for treatment according to the CRYO-ROP study.

Prethreshold disease is less than threshold disease and has been defined by the early treatment of retinopathy of prematurity (ETROP).

SCREENING FOR RETINOPATHY OF PREMATURITY

Goal of Screening

The purpose of screening is to identify preterm infants that require treatment for ROP, while minimizing the number of stressful examinations.

Fig. 6: Stage 4 ROP with subtotal retinal detachment (*For color version see plate 3*)

Age at Onset and Rate of Progression

While the propensity of a baby to develop severe ROP is influenced by many factors such as the degree of prematurity and neonatal events, the time at which it develops appears to be largely independent of these events. This knowledge has proved useful in the design of ROP screening guidelines for it is known that most babies—whatever the degree of immaturity and illnesses—develop ROP at a time which can be predetermined to a significant degree, and which progresses according to PMA.

Screening Guidelines

In more than 90 percent of infants with ROP, the course is one of spontaneous arrest and regression with little or no residual effects or visual disability. In less than 10 percent of infants there is progression toward severe disease, with significant extraretinal vasoproliferation, cicatrization, detachment of the retina, and impairment of vision. Permanent structural and visual damage occurs only in stage IV of ROP. Therefore, adequate treatment should be initiated well before this stage is reached. The aim of screening is to identify all treatable neonates. It is also necessary to keep the screening within a specific protocol so as not to waste resources on low risk neonates.

The disease is considered to be more severe if it is present in zone I, has a “plus” component or involves more clock hours of the retina. ROP in zone III is rarely aggressive and normally regresses (involutes) without adverse consequences. A good screening program ensures early detection and timely intervention. Treatment is done by ablation of the peripheral avascular retina using cryo or laser therapy and should be considered within 48 hours of diagnosis.

Whom to Screen?

Infants with a birth weight of less than 1500 g or with a gestational age of 34 weeks or less, as well as selected infants between 1500 and 2000 g with an unstable clinical course who are believed to be at high-risk by their attending pediatrician or neonatologist, should have at least 2 fundus examinations performed after pupillary dilation using binocular indirect ophthalmoscopy to detect ROP. Nurseries can set up their individual protocols depending on the level of neonatal care available. The location and sequential retinal changes, if any, should be recorded using the International Classification of Retinopathy of Prematurity. One examination is sufficient only if it unequivocally shows the retina to be fully vascularized bilaterally.

When to Screen?

The first examination should normally be performed between 4 and 6 weeks of chronologic (postnatal) age or, alternatively, within the 31st to 33rd week of postconceptional or postmenstrual age (gestational age at birth plus chronologic age), whichever is earlier. As ROP usually develops after 5 to 6 weeks of age, examinations are generally not needed in the first 4 weeks after birth. The timing of the initial screening examination may be adjusted appropriately on the basis of local incidence and onset of ROP or the presence of other recognized risk factors. The initial screening examination and subsequent examinations should be timed to permit sufficient time for treatment. Scheduling of follow-up examinations is determined by the immaturity of the retina and the stage of ROP at the first examination. The crucial window period for the development of ROP is 37 to 42 weeks (Fig. 7). If the retinal vascularization is incomplete but no ROP is detected, follow-up examination should be planned at approximately 2 weeks intervals until vascularization

proceeds into the periphery. Weekly examination is done in mild ROP or if the retinal vasculature is immature with vessels ending in zone I but no ROP in that zone. Any disease in zone I is critical and must be monitored closely. This area is very small and changes can occur very quickly, sometimes within days. Twice weekly examination is recommended for more severe ROP. Parents of infants with ROP should be informed of the nature and possible consequences of this disorder throughout the infant's hospital stay, beginning at the time of first diagnosis and continuing on an ongoing basis with updates on its progression during hospitalization. Responsibility for examination and follow-up of infants at risk for ROP must be carefully defined by each neonatal intensive care unit. Unit specific criteria for examination for ROP should be established for each neonatal intensive care unit by consultation and agreement between neonatology and ophthalmology services. These criteria should be recorded and should automatically trigger scheduled ophthalmology examinations. If hospital discharge or transfer to another neonatal unit or hospital is contemplated before retinal maturation into zone III has taken place, the availability of appropriate follow-up ophthalmologic examination must be ensured and specific arrangement for that examination must be made before such discharge or transfer occurs. If responsibility for arranging follow-up after discharge is delegated to the parents, it must be clearly understood by the parents that blindness is a possible outcome, that there is a critical time window to be met if treatment is to be successful, and that timely follow-up examination is essential to successful treatment.

How to Screen?

Screening should be done in a temperature-controlled room/nursery as premature babies are susceptible to hypothermia, bradycardia, apneic episodes and fall of oxygen saturation. A dilated fundus examination using a 20 diopter and 28 diopter lens, with scleral depression if necessary. Pupillary dilatation is done with phenylephrine 2.5 percent and tropicamide 0.5 to 1 percent instilled 3 times at 10-minute intervals, one hour before examination. The eye examination is stressful for babies, it may cause bradycardia, which can be reduced by nesting.

The first part of the examination should be external, with identification of iris rubeosis, if present. The next part of the examination should be the posterior pole, with identification of any plus disease or straightening of the vascular arcades. The eye is rotated to identify the presence or absence of zone 1 disease (if the ridge and the optic nerve are present in the same view, this usually implies zone 1). If the nasal vessels are not at the nasal ora serrata, this is still zone 2. If the nasal vessels have reached the nasal ora serrata, the eye is in zone 3.

<i>Zone II</i>	<i>Zone II</i>
Plus disease with stages 2 or 3	Stage 3 without plus disease
<i>Zone I</i>	<i>Zone I</i>
Plus disease with stages 1, 2, or 3	Stages 1 or 2 without plus disease
Stage 3 without plus disease	

TREATMENT OF ACUTE ROP

The CRYO-ROP study confirmed the success of cryotherapy treatment versus nontreatment. Over the past decade, cryotherapy has very largely been succeeded by (argon/diode/double frequency YAG) retinal laser treatment. Laser is now the preferred mode since the most severe forms of disease are more easily treated with laser than with cryotherapy. Although more time-consuming, it is less traumatic to the baby (Table 1).

Rationale for Treatment

The stimulus for abnormal vessel growth comes from the peripheral nonvascularized hypoxic retina. The fundamental principle of treatment is to remove, by cryotherapy or laser, the stimulus for vessel growth by ablating the peripheral avascular retina.

Criteria for Treatment

The indication for treatment as reported in the CRYO-ROP study was threshold ROP. The term threshold denotes the ROP stage at which spontaneous and complete resolution is unlikely and the risk of blindness is predicted to be close to 50 percent. However, although the CRYO-ROP study improved outcome in 44.4 percent of eyes with a history of severe ROP, this is far from ideal and the need for more effective approaches to treatment is required. Further studies, such as that published recently by the Early Treatment for Retinopathy of Prematurity Cooperative Group (ETROP), have addressed this issue.

Earlier the indication for treatment was threshold ROP but now the ETROP Study recommends treating eyes before threshold is reached because the outcome of some eyes treated once they have developed threshold disease has been poor. This has resulted in modification of the currently accepted treatment guidelines and offers hope for the most difficult ROP cases. Other reported trials have shown morphological variations in extreme

prematurity that do not follow the previous clinical criteria. These findings may also lead to the need to modify the current guidelines for treatment in extreme prematurity. *What is ETROP?* The Early Treatment for Retinopathy of Prematurity (ETROP) study, published in December 2003, has demonstrated that earlier treatment of selected cases of prethreshold retinopathy of prematurity (ROP) at high-risk to progress to retinal detachments gives better overall ROP outcomes than treatment at threshold severity of the disease.

The study's criteria called for treating patients who fell into these three categories.

Type I ROP

- Zone 1, any stage of ROP with plus disease
- Zone 1, stage 3 without plus disease
- Zone 2, stage 2 or stage 3 with plus disease

The following schedule is used for screening infants who do not yet meet criteria for treatment:

TYPE II ROP

- Twice a week if there is
Zone II, no plus, stage 3
Zone I, no plus, stage 1 or 2
- Every week if the infant is near type 2
Zone II, no plus, stage 2
Zone I, no ROP, immature
- Every 2 weeks if less concerning
Zone II no plus, immature or stage 1

Timing

Timing is critical and should be undertaken within the treatment window. Type 1 ROP should be treated within 24 to 48 h from the identification of ROP reaching a criteria for treatment (Fig. 8).

PREPARING FOR THE PROCEDURE

Preparing the Parents

The parents must be informed about the nature of the disorder, the risk of blindness and the expected success rate.

Preparing the Baby

Close supervision and monitoring throughout the procedure can best be provided in the neonatal unit. Cryotherapy and laser treatment are painful and/or lengthy procedures and a team effort with the support of the neonatologist is required. Full monitoring is essential during the procedure. A separate room, usually in the NICU should be used for laser treatment and safety goggles should be worn by all staff present.

	I	I+	II	II+	III	III+
Zone I	HR	THRESHOLD ROP-TREAT (8 cumulative or 5 contiguous clock hours)	HR	THRESHOLD ROP-TREAT (8 cumulative or 5 contiguous clock hours)	THRESHOLD ROP-TREAT (8 cumulative or 5 contiguous clock hours)	THRESHOLD ROP-TREAT (8 cumulative or 5 contiguous clock hours)
Zone II					HR	THRESHOLD ROP-TREAT (8 cumulative or 5 contiguous clock hours)
Zone III						+/– May treat if follow up is poor (not according to ETROP)

Fig. 8: Treatment and follow-up criteria for ROP according to ETROP

Preparing the Eye

This is similar to the preparation for screening.

Procedure

Cryotherapy is applied externally through the sclera, whereas laser therapy uses both argon-green and diode wavelengths delivered through a portable indirect ophthalmoscope. Systemic complications are rare if treatment is applied with adequate monitoring. Ocular complications can occur with both treatments, but are usually minor and relatively rare.

Postoperative management: No postoperative medication is required following laser treatment. Topical antibiotic ointment is applied for 5 days following cryotherapy. The retina is examined 5 to 7 days later by which time plus disease should show signs of subsiding.

Retreatment

With effective treatment, retreatment is not frequently required, but if it is, it should be undertaken as soon as it is obvious that regression has not started, usually within 7 to 10 days.

Regression: Post-treatment it takes 6 to 12 weeks to regress completely.

LONG-TERM FOLLOW-UP

All infants with stage 3 disease and those who have been treated should be kept under review for at least the pre-school years to monitor the development of vision, refractive status, and ocular motility. The incidence of strabismus is between around 6 percent to over 30 percent. Myopia is a well-known complication of ROP with its onset in infancy and progression during the first year after birth but with relative stability thereafter. Long-term complications include an increased risk of developing retinal detachment, which may occur any time during life.

MANAGEMENT OF ADVANCED DISEASE

Parents will want to know if anything can be done if cryotherapy or laser treatment has failed to stop the progression of the disease. There are a number of aspects to consider.

Vitreoretinal Surgery

Anatomical retinal alignment can be obtained in a significant proportion of cases, but to date the visual results are extremely dismal with almost all infants gaining no improvement with respect to vision. It is critical that during any discussion parents are made aware of the difference between anatomical and functional success. It should be pointed out that complex surgery may put any residual useful vision at risk and leave a painful eye that requires long-term pain control. Multiple operations may be required, which impacts the psychological development of the infant. Stage IV is treated by an encircling band. Stage IV B and stage V are treated by vitrectomy.

THE ROP EPIDEMICS

The literature contains many references to two ROP epidemics. The first occurred in the 10 to 15 years following 1942 and was due mainly to high, unrestricted and unmonitored, oxygen administration. The excessive amounts of oxygen administered at that time almost certainly swamped all other ROP risk factors, even the effect of immaturity, so that in this era blinding ROP affected a wide birth weight range of premature babies. Because the survival of babies under 1000 g birth weight in the 1940s was under 10 percent, most of those babies blinded at this time had a birth weight exceeding 1000 g.

The second 'epidemic' commenced slowly in the 1970s and continues to the present time. Advances in neonatal intensive care, including the meticulous administration and monitoring of oxygen administration, have largely eliminated the risk of severe ROP for the more mature

pre term babies, so that nowadays severe ROP is mostly confined to babies of birth weight under 1000 g. Consequently the second epidemic reflects mainly the increased survival of extremely premature babies. While in high-income countries, increased survival is the main ROP factor, standard of care still contributes to its development. In middle-income countries the prevailing health care environment contains elements of both epidemics, namely increased survival but with limited resources that do not permit the highest quality of neonatal care.

In India, we have all the phases of the epidemic and babies up to 2 kg have been recorded to have ROP stage III. In nurseries with a high quality of care (less sepsis, decreased oxygen use with monitoring, decreased transfusion) ROP is limited to children < 1 kg.

SETTING UP A ROP PROGRAM FOR SCREENING AND TREATMENT

All hospital nurseries, which are managing babies of birth weight < 1500 gm should have a screening program. It is the duty of the neonatologist to send all babies for screening. The neonatologist should identify an ophthalmologist, preferably a retinal surgeon who is well-versed with indirect ophthalmoscopy. The ophthalmologist should be trained in a center where ROP screening is done regularly as it takes time even for a trained retinal surgeon to be well-versed with retinal evaluation in a neonate. The neonatologist and the ophthalmologist should jointly decide the protocol for screening. Initially all children up to 34 weeks and < 1.8 kg maybe examined to assess the incidence of ROP in the nursery and the weight and gestation limit, e.g. if a 1.8 kg and 34 weeks is the biggest child who develops ROP stage I, this should be the limit for screening. The data should be reviewed every year and the screening criteria reduced. As the nursery care improves, the rate of ROP will reduce. In our nursery at Sir Ganga Ram Hospital the criteria have been revised from 34 weeks and 1.5 kg in 1994 to 1.2 kg and 30 weeks in 2005.

The second stage of the program is the treatment part. All hospitals may not have in-house facilities for laser/cryotherapy. With time laser has become more popular in view of less morbidity. If your city has a laser center for ROP, then the neonatologist must coordinate with it. Nowadays laser machines have become portable and can be transferred to the nursery.

The third stage of the program is treatment for stages IV and V. This entails scleral encircling band for stage IV and vitreoretinal surgery for stage V under general anesthesia, and is done in a few specialized centers only. Surgery for stage V ROP is still controversial as the visual results are poor despite anatomical success.

SUMMARY

Blindness due to ROP is preventable. The incidence of ROP will continue to increase with the increasing survival rates of premature babies. Relevant information regarding the screening and treatment of RP needs to be disseminated among neonatologists and ophthalmologists.

Facility-based Newborn Care

Vikram Datta, Bhanu Bhakhri

BACKGROUND

Reproductive and Child Health (II) Program of the Ministry of Health and Family Welfare, Government of India aims to reduce Infant Mortality Rate (IMR) and Under-Five Mortality Rate (U5MR) in accordance with the fourth Millennium Development Goal (MDG).

In India, IMR was estimated to be 50/1000 live births in year 2009 (SRS 2009). Of these 50 deaths, 35 were attributed to deaths in neonatal period (first 28 days of life) and further, 27 of these 35 were during first 7 days of life (early neonatal deaths). Hence, approximately half of the deaths in first year of life occur during first week of life. Neonatal mortality (NMR) contributes to about two-thirds of infant deaths and nearly half of all under 5 deaths. Though in recent years, a modest decline has been observed in IMR in India, NMR appears to be contributing considerably to U5MR and IMR (Table 1). Hence, there is an increasing need to focus on newborn care and survival for significant reduction in IMR and U5MR.

Prematurity/low birth weight, birth asphyxia and infections, the three major causes of early neonatal death account for majority of all neonatal deaths¹ (Fig. 1).

Most of these morbidities can be managed at household and peripheral health facilities and deaths due to them can be prevented.

Introduction of the Janani Suraksha Yojana (JSY) scheme and Integrated Management of Neonatal and

Childhood Illnesses (IMNCI and F-IMNCI) programs has resulted in an increased number of sick newborns presenting to referral hospitals. Provision and delivery of services for both essential newborn care and care of sick newborns in the existing health facilities at the district and subdistrict level has however been found lacking.

THE NEED OF FACILITY BASED NEWBORN CARE

Facility based newborn care (FBNC) assumes significant importance by aiming at strengthening the care of sick, premature, low-birth-weight newborns at the various levels of facilities right from the moment of birth through the neonatal period. It was conceptualized by Ministry of Health and Family Welfare, Government of India under the National Rural Health Mission (NRHM) and its Reproductive and Child Health Programme (RCH II) and operationalized units started in year 2006. The guidelines for FBNC have been put together based on recommendations of an expert group including experts from medical colleges, professional bodies—National Neonatology Forum (NNF), UNICEF, WHO, USAID and NIPI.²

Table 1: Child mortality indicators: Indian scenario			
	1990	Current (2011)	MDG by 2015
Under 5 mortality rate (U5MR)	107	64	36
Infant mortality rate (IMR)	80	50	27
Neonatal mortality rate (NMR)	53	34	20

Fig. 1: Direct causes of neonatal deaths (Lancet 2005)

LEVELS OF NEWBORN CARE AT HEALTH FACILITIES

Based upon level of health facility catering to varying magnitude of population 3 levels of centers for neonatal care has been introduced under FBNC (Table 2).

Newborn Care Corner (NBCC)

This is a space within the delivery room in any health facility where immediate care is provided to all newborns at birth. This area is mandatory for all health facilities where deliveries are conducted. The area of about 20-30 feet is equipped with radiant warmer and resuscitation kits. One doctor and one staff nurse (or ANM at subcenter) is designated to NBCC to ensure appropriate functioning of the corner. All the doctors and nurses who attend the deliveries are trained in Navjaat Shishu Suraksha Karyakram (NSSK), a 2-day training program in basic newborn care and resuscitation rolled out with support from the IAP and NNF.

Newborn Stabilization Unit

Newborn stabilization unit (NBSU) is a facility within or in close proximity of the maternity ward where sick and low birth weight newborns are cared for during short periods. All FRUs/CHCs, catering to less than 3000 people, have a neonatal stabilization unit, in addition to the newborn corner. For a 4 bedded NBSU, 2 beds from postnatal wards

are dedicated for rooming in. The NBSU are equipped for provision of resuscitation and temperature maintenance. One trained doctor is stationed at stabilization unit. At least one full-time staff nurse trained in newborn care per shift is available. The staff at NBSU is trained in facility based IMNCI (F-IMNCI).

Newborn presenting with any of the following signs to a facility with neonatal stabilization unit requires admission for initial stabilization and transfer to SCNU:

- Apnea or gasping
- Respiratory distress (Rate >70/ minute with severe retractions/grunt)
- Hypothermia <35.4°C
- Hyperthermia (>37.5°C)
- Central cyanosis
- Shock (Cold periphery, with CFT >3 seconds and weak and fast pulse)
- Significant bleeding that requires blood or component transfusion.

Newborns, who after assessment and stabilization, can be managed at stabilization unit:

- Newborns with respiratory distress, having respiratory rate 60-70/ minute without grunting or retractions (for observation and oxygen therapy)
- Newborns with gestation less than 34 weeks or weight <1800 g (for observation and assisted feeding)
- Newborns with hypothermia and hyperthermia who are hemodynamically stable after initial stabilization

Table 2: Centers for neonatal care under FBNC

Health facility	NBCC	NBSU	SCNU
Health facility	Primary health center (PHC)/Subcenter (SC) identified as MCH Level I	Community health center (CHC)/ First referral unit (FRU) identified as MCH Level II	District hospital identified as MCH Level III
Minimum bed strength (area in sq. ft.)	1 (20-30)	4 (200)	12 (1000)
Minimum trained technical staff	1 doctor and 1 nurse	1 doctor and 4 nurses	3-4 doctors and 12 nurses
Care at birth	Resuscitation, infection control, warm chain, breastfeeding and weighing	Resuscitation, infection control, warm chain, breastfeeding and weighing	Resuscitation, infection control, warm chain, breastfeeding and weighing
Care of normal newborn	Breastfeeding and feeding support	Breastfeeding and feeding support	Breastfeeding and feeding support
Care of sick newborn	Identification and prompt referral Immunization services	Management of infants >1800 gm, neonatal jaundice, sepsis. Stabilization and referral of sick newborns and those <1800 gm at birth Immunization services	Management of infants <1800 gm and all sick newborns (except requiring assisted ventilation or major surgery) Follow-up services Referral services Immunization services
Approximate indicative cost for set up (in INR)	1,05,000	7,50,000	51,00,000

- Newborns with jaundice requiring phototherapy
- Neonates with sepsis who are hemodynamically stable, for observation and antibiotic therapy.

Special Care Newborn Unit (SCNU)

Any facility with more than 3,000 deliveries per year should have an SCNU (most district hospitals and some subdistrict hospitals would fulfill these criteria). The minimum recommended number of beds for an SCNU at district hospital is 12. However, if the district hospital conducts more than 3000 deliveries in a year, 4 beds are added above 12 for every 1000 additional deliveries. Additional one third beds (4 for 12 bedded SCNU) are available for rooming in. Table 3 provides calculation for estimating number of beds required for a SCNU.

A 12-bedded unit is managed by 1 pediatrician trained in neonatology, supported by 2 or 3 medical officers trained in FBNC. Such a unit will also have 3 nurses in each shift, dedicated support staff, round the clock. In addition, a part time lab technician and a data operator are available for the unit. The staff posted at the SCNU undergoes intensive 4 day training focusing on the skills on clinical management, housekeeping and maintenance of the equipment followed by 2 weeks observership at one of the recognized centers. SCNU provides special care (all care except assisted ventilation and major surgery) for sick newborns.

Indications for Admission to the SCNU are:

- Birth weight <1800 g or gestation <34 weeks
- Large baby (>4.0 kg)
- Perinatal asphyxia
- Apnea or gasping
- Refusal to feed
- Respiratory distress (Rate >60/minute or grunt/ retractions)
- Severe jaundice (Appears <24 hrs/Stains palms and soles/lasts >2 weeks)
- Hypothermia <35.4°C, or hyperthermia (>37.5°C)
- Central cyanosis
- Shock (Cold periphery with CFT >3 seconds and weak and fast pulse)
- Coma, convulsions or encephalopathy
- Abdominal distention

- Diarrhea/dysentery
- Bleeding
- Major malformations.

Criteria for Transfer from SCNU to the Step Down

- Babies whose respiratory distress is improving and do not require oxygen supplementation to maintain saturation
- Babies on antibiotics for completion of duration of therapy
- Low-birth-weight babies (less than 1800 g), who are otherwise stable (for adequate weight gain)
- Babies with jaundice requiring phototherapy but otherwise stable
- Babies admitted for any condition but are now thermodynamically and hemodynamically stable.

Criteria for Discharge from SCNU to Home

- Baby is able to maintain temperature without radiant warmer
- Baby is hemodynamically stable (normal CFT, strong peripheral pulses)
- Baby accepting breastfeeds well
- Baby has documented weight gain for 3 consecutive days; and the weight is more than 1.5 kg
- Primary illness has resolved.

Operational Steps for Planning and Rolling Out Facility based Newborn Care in India

- *National collaborative center* for FBNC at Kalawati Saran Children's Hospital, New Delhi, will provide technical expertise and overall support to the government for effective implementation and monitoring of the progress in the states. Its functions will include preparing and updating technical guidelines, norms and protocols, monitoring the progress and quality, analyzing reports, mentoring some regional/state collaborative centers, providing recommendations to the Ministry of Health and Family Welfare to improve the implementation and to build capacity of the regional and state collaborative centers.
- *Regional collaborative centers* are the existing centers of excellence in newborn care (e.g. King Edward Memorial Hospital, Mumbai, PGIMER, Chandigarh and Institute of Child Health, Chennai). They provide technical support in operationalization of newborn care facilities, establishing a monitoring system, and conducting quality assessment.
- In addition, a state medical college is recognized as state collaborative center for capacity building of staff and administrators, establishment of recording and reporting system and operational research.
- Districts with high IMR and high institutional delivery rate are recognized as high priority districts for setting up SCNUs.

Table 3: Number of beds required for SCNU

Average number of live births in last 2 years	A
Number of live births requiring special care	B = (15% × A)
Number of bed days required (average 7-day stay)	C = (B × 7)
Number of special care beds required	D = C/365
An extra allowance of 30% beds for extramural births	E = D × 30%

Table 4: Newborn care facilities a district having one district hospital with more than 3,000 deliveries per year, five FRUs, and twenty 24 x 7 PHCs

Health facility	Services	Numbers
Primary health care/MCH I	Newborn care corners in labor rooms	20
FRU/ Community health center/MCH II	Newborn care corners in labor rooms	5
	Newborn care corners in OT	5
	Newborn stabilization unit	5
District Hospital/MCH III	Newborn care corners in labor rooms	1
	Newborn care corners in OT	1
	Special care newborn unit	1

- Three tiered system of facilities for newborn care in a district is given in Table 4.
- A *multidisciplinary team* composed of doctors, civil work team and biomedical engineers oversee the overall assessment, civil work and refurbishment plans at the district and state level.
- *Record keeping:* Using a standard format, units submit a case record based reports to the state health authorities and collaborative center. The analysis of these reports is used for assessment of the performance of the units which are then provided appropriate feedback.
- Adherence to standard operating procedures for housekeeping and for clinical care of admitted newborns is critical for ensuring quality care at the facilities.
- *Role of NNF*
 - Trainings 4 day FBNC (support, develop pool of national and state trainers)
 - Development and revision of training modules and toolkit
 - Mentoring visits, Quality assurance
 - Handwashing audits, KMC Audits
 - Accreditation of operationalized units under process for linkage with RSBY
 - Equipment trouble shooting guidelines being developed
- *Development of Transport Model:* Free services are provided for transport of pregnant women and sick newborn across the health facilities. The system is regulated by call center based operation and in this context

Shivpuri district of MP has developed a lead model for others' reference.

List of Clinical Protocol Included in FBNC Training Module

- Triage of sick newborns
- Assessment and treatment of newborns displaying emergency signs
- Criteria for admission to SCNU and criteria for transfer to step-down unit and discharge
- Indication of admission to Neonatal Stabilization Unit (NSU)
- Grading and management of hypothermia
- Expression of breast milk
- Assisted feeding of low birth weight neonates
- Intravenous fluid therapy for newborn
- Management of hypoglycemia
- Assessment and management of Jaundice in the newborn
- Assessment and management of respiratory distress
- Assessment of neonatal sepsis
- Administration of commonly used drugs
- Resuscitation algorithm
- Management of the newborn with seizures
- Administration of Dopamine in a newborn with hemodynamic compromise
- Checklist for assessment and management of a newborn requiring special care (remember by mnemonic 'TABCFMFMCF' for temperature, airway, breathing, circulation, fluids, medication, feeding, monitoring, communication and follow-up)
- Identifying Intrauterine Growth Retardation in a newborn
- Assessing gestation of the newborn baby: Expanded New Ballard Score
- Housekeeping protocols
- Breastfeeding.

The detailed discussion of the protocols is beyond the scope of this chapter; interested readers are referred to 'Facility based Newborn care Operational Guide-Guidelines for Planning and Implementation' for further details.

FBNC: VISION AND CHALLENGES

It has been estimated that such health facility based interventions can reduce neonatal mortality by as much as 25 to 30 percent.³ Under the program, so far, 274 SCNUs, 1124 NBSUs and 7413 NCCs have been operationalized till June 2011. Government of India plans to have atleast one SCNU in each district supported by network of NBSU at first referral units, and newborn care corners in each "delivery-point". However, with the expansion of the network, some

of the challenges which have been recognized are integration of obstetric-newborn care, raising a class of trained personnel and mentoring support, maintenance of quality assurance system for delivery of compassionate care at all levels and to strengthen the follow-up of graduates from these facilities for monitoring of the outcomes, as a barometer of the impact of FBNC on the community.

At the preliminary stage, FBNC appears to deliver promising results in certain districts. The replication of the model in other partner states is expected to be an important step to reaffirm community trust in health care system and in turn, strengthen the hopes for achieving the targets of MGD's in India.

Rational Antibiotic Therapy

YK Ambdekar

INTRODUCTION

Infections are common in children and fever is a common presentation. Fever does not equate with infection and not necessarily bacterial infection that may justify an antibiotic. After all, viral infections are common in the community and should not be treated with an antibiotic. Further, not all bacterial infections deserve an antibiotic prescription. However, antibiotics are prescribed for majority of children presenting with fever. In fact they may also be prescribed for children who have no infection as in case of cough due to hyperreactive airway disease. Thus antibiotics are often prescribed without proper diagnosis for fear of probable bacterial infection and antibiotics are often changed or multiple antibiotics used due to fear of worsening condition. Misuse of antibiotics in this way leads to increasing drug resistance that has become a major concern today. Besides, irrational use of antibiotic may suppress but not control infection that would pose difficulty in diagnosis with increased morbidity and risk of mortality. Thus, improper antibiotic use is a threat to the community and also to an individual patient. If this trend continues, it may not be long before even a simple infection may not be amenable to drug therapy.

WHEN SHOULD AN ANTIBIOTIC BE PRESCRIBED?

Attempt a Bacteriological Diagnosis

Antibiotic is indicated only in case of bacterial infection. It is ideal to attempt bacteriological diagnosis in every child with suspected bacterial infection. Though it is not practical in routine office practice. However, few conditions demand proof of bacterial infection as in case of urinary tract infection and typhoid fever. UTI in children is a potential serious disease with a risk of permanent renal damage if not properly diagnosed and

treated. Typhoid fever being a bacteremic infection, blood culture is often positive and technically, it is easy to culture *Salmonella typhi*. It is therefore expected that UTI and typhoid fever are bacteriologically diagnosed as often as possible and empirical treatment is not justified. In case culture facilities are not available, at least, circumstantial evidence should be collected before embarking on specific antibiotic therapy.

Circumstantial Evidence of Bacterial Infection

Typical clinical syndrome in an acutely febrile child may strongly suggest bacterial infection that may not need further proof for rational antibiotic prescription. Acute tonsillitis is clinically diagnosed by finding beads of pus on inflamed tonsils and tender submandibular lymph nodes. Loose stools with blood and mucus and abdominal cramps suggest acute bacillary dysentery. Localized chest findings in an acutely febrile child who develops tachypnea denotes bacterial pneumonia that may be confirmed by chest X-ray but even without chest X-ray would justify antibiotic therapy.

Laboratory evidence of bacterial infection should not be considered in isolation without clinical correlation. Neutrophilic leucocytosis and high CRP may favor bacterial infection but not adequate enough by themselves to consider antibiotic therapy.

WHEN THERE IS NO CLUE TO DIAGNOSIS

This is most common situation in routine office practice during first few days of onset of fever. Generally, one can arrive at reasonably correct diagnosis only after disease evolves over few days after onset of symptoms. It means that correct diagnosis is not possible in a febrile child in first few days with exception cited above such as tonsillitis and bacillary dysentery. At such stage, it is important to assess risk of waiting without specific action in an acutely febrile child.

Following situations in acutely febrile child are considered to be at risk of serious bacterial infection that demands urgent specific action:

- Age <3 months
- Severe PEM
- Immunosuppressed state
- Behavioral abnormality—lethargy or extreme irritability
- Significant oliguria or anuria
- Tachycardia and tachypnea disproportionate to degree of fever.

In such situations, laboratory tests should be ordered before starting empirical antibiotic and decision taken for need for hospitalization. Laboratory tests may be prioritized on individual merits and they include CBC, urinalysis, chest X-ray, blood and urine culture and CSF examination.

WHEN THERE IS NO CLUE TO DIAGNOSIS BUT SAFE TO WAIT

In absence of risk factors in a febrile child, it is rational to wait and observe progress without antibiotic therapy. Fever should be controlled with paracetamol. Parents must be counseled about danger symptoms such as behavioral abnormality and reduced urine output that demand reporting to medical facility. Periodic clinical examination is necessary over next few days to pick up clinical clues to diagnosis. Attempt must be made to differentiate acute bacterial infection from acute viral infection. It is possible to a reasonable extent by detailed analysis of history of fever as depicted in Table 1.

Table 1: Look for clues to diagnosis

	<i>Bacterial</i>	<i>Viral</i>	<i>Malaria</i>
Degree at onset	Moderate	High	High
Rhythm	Regular	Regular	Irregular
Response to paracetamol	Average	Good	Good
Interfebrile state	Sick	Normal	Normal
Progress on D3-4	Persisting	Better	Variable
Contact history	None	Positive	None

In case of suspected viral infection, no antibiotic is justified. In case of suspected bacterial infection, consider

relevant laboratory tests before starting empirical antibiotic. Empirical antibiotic selection should be based on local epidemiological observation and experience. In case of suspected malaria, one should look for malarial parasite in blood smear before prescribing antimalarial therapy.

WHEN ANTIBIOTIC FAILS IN SUSPECTED BACTERIAL INFECTION?

Antibiotic rarely fails in routine office practice in case of community-acquired infection in a normal host. One should expect response to antibiotic within 3 to 4 days. If there is no response, it calls for reassessment.

Firstly confirm whether it is infection and if so bacterial infection. This may be done by repeated physical examination supported by repeat laboratory tests. Choice of antibiotic and its route of administration may be a factor responsible for poor response. If bacterial infection and choice of antibiotic are reasonable confirmed, look for complications such as empyema in case of bacterial pneumonia or subdural collection in case of meningitis. At times, poor response may be due to iatrogenic factor such as catheter related infection or nosocomial infection in a hospitalized setting. Only when all such factors are ruled out that one may consider drug resistance. It is ideal even at this stage to send blood culture and then change to best considered empirical antibiotic. However, if this change also fails, bacterial infection is ruled out and one must search for alternate diagnosis. It is not wise to persist with empirical antibiotic trial beyond one change.

SUMMARY

Rational antibiotic therapy is the need of the hour. Empirical antibiotic therapy has a place in routine practice but only with rational approach. It includes assessing risk of waiting, clinically evaluating probable etiology of fever supported by relevant laboratory tests, repeated observation to monitor progress, selecting appropriate empirical antibiotic and reassessment in case of poor response. With indiscriminate antibiotic use, there has been increasing drug resistance and time has come to change this trend lest we are defeated by simple infections.

Adverse Drug Reactions and Pharmacovigilance

DC Dhasmana

INTRODUCTION

Humans are fond of taking medicines for their sufferings since time immemorial. At present, consumption of medicines has become a normal concept of daily life, being used in all trivialities. The huge list of available formulations and drugs coupled with enormous therapeutic advances is tempting to all clinicians to prescribe them. The Druglist continues to grow especially in recent times with a lot of newer entries as a result of high tech pharma products, new vaccines, new dosage forms, newer routes of administration besides new therapeutic claims of existing drugs.

India is a vast and diverse country with almost 1.2 billion population, at present with many diverse characteristics with social, economic and cultural paradigms. As population continues to grow, the disease pattern and magnitude grows in parallel to increased drug consumption in the society. Habitual prescribing, misuse and abuse of drugs are common. Simultaneous growth of nonprescription (OTC) drugs and self-medication contributes heavily to overall drug consumption. With increasing burden of non infectious/degenerative diseases, poly pharmacy is a common practice inviting drug-drug interactions. Many alternative therapies, herbal medications, nutritional supplements added to complicate the issue of drug interactions further.

Indian Pharmaceuticals, worth Rs. 90,000 crore, are growing at a pace of 12 to 14 percent per annum with ~25 percent export growth per year according to one estimate. They are competing in finding a share of the market by infusing many new combinations and formulations with special physical/ technological properties. India, in fact has established a global pharmacy of generic drugs, producing quality drugs at affordable prices. More over India is coming up as global hub for clinical trials in drug discovery programs too.

Harmful effects of drugs as referred to adverse drug reactions (ADRs) are as old as medicinal use. In fact, a common dictum is 'a drug that does not produce an ADR is not a drug at all'. Incidence of ADR's is contributed by poly pharmacy, OTC drug use, alternative medications/ nutritional supplements equally. ADRs *per se* are one of the leading causes of morbidity and mortality worldwide. ADRs may range from mere inconvenience to serious disability and may contribute to 3 to 6 percent of hospital admissions and death (2-12%).¹ They commonly occur in hospital setting where more serious patients are managed with multiple drug therapies. Further, managing ADRs put a huge financial burden on the health care delivery and the total cost involved may be more than the individual cost of managing cardiovascular, diabetes, cancer and HIV disorders.²

Small group of widely used drugs accounts for a disproportionate number of ADRs. Almost 50 percent of drugs produce unusual and unpredictable serious ADRs only after marketing. Moreover, newly marketed drugs need more care on ADRs as they are not exposed to large number of patients in a variety of situations, over a long period of time for want of their remote manifestations. Full range of ADRs may not be known until the drug is already in use for many-many years. Thus, the irony is that long-term safety of drug use and rare ADRs are practically unknown at the time of its introduction in the market. Further, the special population of patients, i.e. pediatric, elderly, pregnant and lactating women, patients with multiple disorders etc. make them more prone to develop ADRs. Spectrum and severity of ADRs also varies as the disease pattern, patient population characteristics, prescribing habits, availability of drugs and their quality vary from region to region.

A large number of ADRs (almost more than 50%) could be prevented, if we are aware of them and know

about their mechanisms and predisposition. This is possible only by a close and continual watch on ADRs, their understanding and reporting. Monitoring ADRs is a challenging job in the current scenario for which a robust program is needed. At times, such observed ADRs in the past led to withdrawal of many drugs from the market with big surprises among the public, i.e. Cloquinol, practolol, Benoxaprofen, suprofen, Tacyinafen, Zomepirac, Troglitazone, cerivastatin, lomefloxacin, grepafloxacin, gatifloxacin, Rofecoxib, Astemizole, Terfenadine, alos-etron, phenylpropanolamine, fenfluramine, sibutramine, mibefradil, cannabinoid receptor antagonist—rimonabant, Tegaserod and change in labeling of cisapride, isotretinoin, and many others. To conclude, ADRs, must be predicted, recognized, reported, their mechanism be understood and prevented at all cost keeping in mind the huge economic loss in managing them.

TERMINOLOGIES USED IN ADRS

The following terminologies are used as per WHO recommendations:³

Adverse drug reaction: A response to a drug which is noxious and unintended, and which occurs at doses normally used in man for the prophylaxis, diagnosis, or therapy of disease, or for the modification of physiological function.

Unexpected adverse reaction: An adverse reaction, the nature or severity of which is not consistent with domestic labeling or market authorization, or expected from characteristics of the drug.

Adverse event/adverse experience: Any untoward medical occurrence that may present during treatment with a pharmaceutical product but which does not necessarily have a causal relationship with this treatment.

Side effect: Any unintended effect of a pharmaceutical product occurring at doses normally used in man which is related to the pharmacological properties of the drug.

Signal: Reported information on a possible causal relationship between an adverse event and a drug, the relationship being unknown or incompletely documented previously. Usually more than a single report is required to generate a signal, depending upon the seriousness of the event and the quality of the information.

CLASSIFICATION OF ADRs/TYPES

Workable classification includes:

Type-A: are those that are dose dependent, predictable and are the extension of known pharmacological actions of drugs.

Type-B: are those that are nonpredictable and not so dose dependent and are not explained by the known pharmacological actions of the drugs.

A more elaborate classification is based on Type-A (dose dependent known pharmacological effect), Type-B (non dose dependent; bizarre sensitivity reactions—allergic or idiosyncratic reactions), Type-C (cumulative chronic toxicity-chronic organ damage), Type-D (delayed—carcinogenicity, teratogenicity), Type-E (end of the use effect) and Type—F (negative effect or the failure of the drug efficacy).⁴

FREQUENCY⁵

Frequency of ADRs can be assessed as follows in terms of fractions and percentage:

Very common	>1/10	(>10%)
Common (frequent)	1/100-1/10	(1-10%)
Uncommon (infrequent)	1/1,000-1/100	(0.1-1%)
Rare	1/10,000-1/1,000	(0.01-0.1%)
Very rare	<1/10,000	(<0.01%)

SEVERITY

“Severity” is used to describe the intensity of a specific event/reaction as mild, moderate, severe or lethal; the event itself, however, may be of relatively minor medical significance, i.e. such as severe headache.⁶ Severity assessment can be done by Hartwig et al scale.⁷

VARIABLES THAT DETERMINES THE INCIDENCE AND SEVERITY OF ADRs

Many variables influence the incidence and severity of ADRs as both intrinsic and extrinsic factors play a role. Age being one of the important predisposing factors—both elderly and pediatric age (neonates, infants) being vulnerable.⁸ Others could be sex, immunological, genetic, environmental, socioeconomic, prescribing factors, drug factors, i.e. route, formulation and duration of therapy. Determinants must be explored to understand ADRs leading to their preventability, i.e. Gray baby syndrome due to chloramphenicol in infants and neonates.

SERIOUSNESS³

A serious adverse event or reaction is any untoward medical occurrence that at any dose:

- Results in death
- Requires inpatient hospitalization or prolongation of existing hospitalization
- Results in persistent or significant disability/incapacity
- Is life-threatening

PREVENTABILITY

ADRs almost more than 50 percent are preventable provided that they are anticipated in a clinical situation.⁹ Under reporting due to misconceptions and failure to

disseminate the information because of lack of knowledge as to where, when and how to report the ADRs contributes to nonpreventability. Prior considerations of factors/variables known to modify drug actions often make it possible to prevent ADRs.⁷ Unfortunately despite increased vigilance in western world the number of preventable ADRs remains constant over four decades.¹ Pharmacogenomics may add new dimensions to boost the prevention of ADRs in near future.

DRUG SAFETY ISSUES RELATED TO PEDIATRICS

There is a limited knowledge of drugs in terms of drug dosage, and their safety in neonate, premature neonate, infants, children and adolescents compared to adults. Kinetics and dynamics of drugs are least certain in this age group where there is a rapid transition in physiology, anatomical and functional development over time. Moreover off-label use of drugs is high (~43%) in pediatric age group, increasing particularly the serious ADRs burden.¹⁰

Sulfanilamide elixir dissolved in diethylene glycol deaths, thalidomide disaster, gray baby syndrome, Reye's syndrome being the typical historical examples. Ethambutol causing visual impairment, fluoroquinolones linked to arthropathy, increased phenothiazines sensitivity for extrapyramidal syndromes, sulfa drugs predisposition to kernicterus, tetracyclines causing dental staining, valproic acid induced hepatotoxicity, steroid induced growth and development problems, and antiepileptic induced mental retardation are other examples that are specific in this age group. Study by Ufer et al¹⁰ in Sweden showed anti-asthmatics and antibiotics on top of ADRs producing drug list in pediatrics and most common manifestations were psychiatric and the mucocutaneous inflammatory reactions. Thus, this age group is bound to be most vulnerable to unpredictability of drug actions and their consequences.

PHARMACOVIGILANCE

The early experiences of thalidomide and high oral estrogen contraceptives led to stringent safety requirements during drug development and establishment of spontaneous ADRs reporting system in 1960s.¹¹

Detection of ADRs is a complex issue. Their detection is inefficient due to difficult clinical situations, difficulty in clinical monitoring, diagnostic imprecision, low index of suspicion and nonreporting of ADRs by the clinicians.¹² Early experiences with a new drug are poor predictors of unknown, rare, and long term ADRs in the looser context of their use in the society. To keep a watch on such ADRs, continual post marketing surveillance/pharmacoepidemiological studies are needed for which observational/descriptive designs must be adopted, i.e. cohort studies, prescription event monitoring, case control studies, case

reports, case series and spontaneous reporting system, etc. so as to refine rational use and socioeconomic impact of drugs with possible regulatory changes. The lower cadre of observational studies yields most in detection of ADRs after drug marketing. In this way, the importance of spontaneous ADRs monitoring system is tremendous in surfacing new and previously unrecognized ADR leading to awareness and even regulatory changes or withdrawal of the drug from the market. There is no substitute for such a system in detecting ADRs though even with spontaneous ADRs monitoring system, the occurrence of new and unexpected ADRs after marketing remains unabated that raises questions on the methodology and implementation of predicting ADRs.¹¹

WHO took up the issue of grave public and professional importance of ADRs and came out with a systematic spontaneous reporting system at Uppsala, Sweden in 1968.¹³ The initiative has created a whole new discipline of pharmacovigilance that can be defined as: the science and activities relating to the detection, assessment, understanding and prevention of adverse effects or any other drug-related problems. It is the collection of information on ADRs in a systematic manner to draw meaningful conclusions. The primary aim of pharmacovigilance program (PVP) is to detect early warning signals that are unknown to drug previously. A robust PVP has educative, managerial and regulatory roles to play. ADRs reported to national PVP globally looks to be the most efficient system in generating data on ADRs¹¹ with the help of all stake holders, i.e. Pharma industry, academic and private institutions, practicing physicians, nurses, pharmacists, media, consumers and regulators. The ambit of PVP has lately increased further to cover the food, herbal, biological products including vaccines and medical devices. This is the way one can protect the patients and ensure unsafe drugs to be weeded out of market.

In fact, most of the recent reporting on ADRs leading to withdrawal or change in labeling were the results of such successful national programs worldwide like sibutramine by Italian and Rofecoxib by Canadian PVPs. Even, at times, the spontaneous AEs database through PVP may lead to identification of unanticipated drug benefits for therapeutic exploration.¹²

HOW TO DETECT ADRs?

The physician must exert efforts and keep his eyes and ear open to see and report an ADR. To collect and collate ADRs, all the health care persons/pharmaceuticals and regulatory bodies have to integrate their efforts to generate high quality data as an obligatory national priority. It is to foster the culture of reporting adverse events for which voluntary cooperation of health professionals is a must. A prepared mind with strong index of suspicion is desired in every practicing physician.

CAUSALITY ANALYSIS³

Causality assessment is crucial in PVP as it reflects into safety aspects of drug. It is the causality assessment that makes an adverse event to adverse drug reaction. WHO's direct introspection method is the most common method for this purpose, although many decisional algorithms have also been described in the literature to predict the causality with their own merits and demerits. Basic concept lies in describing, challenge, dechallenge, and rechallenge, previous knowledge and confounding other drug's contribution for suspected ADR in reported adverse event.

As per WHO³, following criteria are used:

Certain: A clinical event, including laboratory test abnormality, is occurring in a plausible time relationship to drug administration, and which cannot be explained by concurrent disease or other drugs or chemicals. The response to withdrawal of the drug (dechallenge) should be clinically plausible. The event must be definitive pharmacologically or phenomenologically, using a satisfactory rechallenge procedure, if necessary.

Probable/likely: A clinical event, including laboratory test abnormality, with a reasonable time sequence to administration of the drug, unlikely to be attributed to concurrent disease or other drugs or chemicals, and which follows a clinically reasonable response on withdrawal (dechallenge). Rechallenge information is not required to fulfill this definition.

Possible: A clinical event, including laboratory test abnormality, with a reasonable time sequence to administration of the drug, but which could also be explained by concurrent disease or other drugs or chemicals. Information on drug withdrawal may be lacking or unclear.

Unlikely: A clinical event, including laboratory test abnormality, with a temporal relationship to drug administration which makes a causal relationship improbable, and in which other drugs, chemicals or underlying disease provide plausible explanations.

Following noncausality terms are also used:

Conditional/unclassified: A clinical event, including laboratory test abnormality, reported as an adverse reaction, about which more data is essential for a proper assessment or the additional data are under examination.

Unassessible/unclassifiable: A report suggesting an adverse reaction which cannot be judged because information is insufficient or contradictory, and which cannot be supplemented or verified.

PHARMACOVIGILANCE PROGRAM OF INDIA

Unlike western countries, there is a dearth of ADRs monitoring in India. Pharmacovigilance program of India I is

still in infancy, in spite of large number of tertiary care centers, a fleet of well trained and skilled healthcare manpower and a blooming pharmaceutical industry. Here, most of the ADRs go under reported.

The regulatory frame work must ensure drug safety of Indian population at all cost. To protect the interest of consumers, the DGHS, Government of India has mandate to facilitate availability of safer and effective drugs and to keep unsafe ones off the market. Presently, this task is given to Indian Pharmacopoeia Commission as National Coordinating Center (NCC) to ensure PVP in India from 2010 onwards. Earlier, PvPI was started in India with the support of WHO in 2004-2008 under DGHS. Realizing its importance, this program is now being indigenously run by the DGHS. The whole idea of PvPI is to generate independent data on Indian population through designated frame work of peripheral centers all over India and then provide evidence based recommendations to industry, the healthcare prescribers, to incorporate in regulatory framework of DGHS and to be the part of the data linkage at Uppsala global monitoring center of WHO as per the agreement. It is a continuous program that has strategic advisory committee, a steering committee, the NCC with signal review committee, core training committee and a quality review panel to look into the whole gamut of ADRs monitoring in India.

Basically, it is an active process of spontaneous ADRs monitoring system that has been given a robust footing to capture all possible meaningful data by new signals generated at the earliest, since we are the major consumers of drugs globally but right now contributing very little towards assurance of safety both nationally and globally.

CONCLUSION

Success of any health care delivery depends heavily on availability of safe, effective and quality drugs at an affordable and reasonable price at all time and all places as per the essentiality of drugs in the area. It is a national priority in the interest of the society to protect the population from potential harm. We cannot escape from ADRs but certainly reduce their occurrence at the same time we can not handle ADRs that are not known beforehand. ADRs must be anticipated in any situation of drug use. A high index of suspicion, good communication and reporting every drug reaction hallmark the quality of the physician. Responsibility of identifying and reporting rests with the practicing physician by careful observation of the drug effects in real world. The facilitatory support for ADRs monitoring can be provided by the system.

Scientifically weaker observational studies, i.e. case reports are more suitable for detecting new unexpected ADRs unlike therapeutic trials and act as whistle blowers. Big hospitals become a hub for detecting ADRs where the

newer drugs are used in all diverse situations. These ADRs can further be put to test by more systematic analysis and quantifying risk. Spontaneous ADRs monitoring looks to be the best suited program for continuous and robust database for any country. Active assistance boosts up the level of reporting and sensitizes and encourages the clinicians to report them. The national program of PvPI has already been made operational to this effect.

To conclude, we all have the concern, responsibility and obligation to strengthen the ADRs reporting program. The fruition of medical practice lies in realizing that each individual is unique and treatment needs to be individualized to suit best under the circumstances.

Newer Antibiotics: New Drugs and New Challenges in Primary Care

Satya Prakash Yadav, Anupam Sachdeva, Vishal Dublish, Vasant Chinnabhandar

INTRODUCTION

Today, the primary care physician is faced with a bewildering array of new antimicrobials to treat common infections. These agents promise to be extremely effective as replacements for time-honored drugs, as prophylaxis, and for the treatment of infections previously requiring prolonged intravenous therapy. The overuse of the newer antibiotics may prove to be ecologically and economically costly. It is feared that the selective pressure from these broad-spectrum agents may burden society with an even greater problem of community-acquired pathogens that are resistant to multiple antibiotics. The specific therapeutic and economic advantages and disadvantages of each class should be considered and the decision to employ these agents should be highly individualized. Several antibiotics have arrived in the market over the past few years. Should they be widely used, or are they best saved for use in exceptional situations by tertiary care specialists?

Each year, Drug Controller of India approves a few new antimicrobial agents. Occasionally, one is quickly

recognized as a potential blockbuster. More often, though, the new drugs are either similar to some already on the market, or they may occupy an important but narrow treatment niche. Methicillin-resistant *Staphylococcus aureus* (MRSA) infections, which were once acquired only in health care settings, are now widespread in communities across the nation. Vancomycin-resistant enterococci (VRE) are present in many tertiary care facilities. Investigators associated with a study of geographic and temporal trends in antibiotic resistance in *Streptococcus pneumoniae* predicted in 2003 that by July 1, 2004, 41 percent of the pneumococci at the CDCs active bacterial core surveillance sites would be resistant to both penicillin and erythromycin.¹ In contrast, they added, only 5% will be resistant just to penicillin, and another 5% would be resistant to erythromycin only.

ANTIBIOTICS

Pathogenic bacteria have demonstrated an unparalleled ability to adapt to changing environments. Of particular concern has been the rapid development of resistance to multiple front-line antibiotics which has severe consequences on patient care and outcomes. Many of these organisms have become important sources of nosocomial infections further adding to morbidity and mortality in already sick individuals. *The Infectious Diseases Society of America* recently published a hit list of bacterial pathogens² whose antibiotic resistance severely impacts the ability to treat infections in the US hospital setting. This list is comprised of *Staphylococcus aureus*, *Enterococcus faecium*, *Acinetobacter baumannii*, *Pseudomonas aeruginosa*, *Klebsiella pneumoniae*, and *Enterobacter spp.* Such data are not available on a large-scale multicenter level in our country as yet. However, the presence of these resistant organisms in our health care institutions due to the lack of coherent guidelines on antibiotic use is an open secret.

Drugs discussed in this article

Daptomycin	Telithromycin
Linezolid	Oritavancin
Ranbezolid	Dalbavancin
Eperezolid	Telavancin
Ertapenem	Iclaprim
Doripenem	Cefditoren
Quinupristin-dalfopristin	Ceftobiprole
Tigecycline	Ceftaroline
Gemifloxacin	

The goal of this chapter is to update primary care clinicians about new antibiotics, their appropriate use and also, importantly, when not to use them. Antibacterials are discussed below, antifungal and antiviral agents are discussed in separate chapters.

A brief review of some new antibiotics is presented below. Several of these recently approved or soon to be approved antibiotics may have a role in primary care practice, while others will probably find more use in tertiary care facilities. In the discussion that follows we have reviewed the more widely used newer antibiotics in some detail. Brief information has also been provided about some drugs which are at the cusp of approval or advanced stages of development.

Daptomycin

Class

Cyclic lipopeptide

Initially discovered in 1980's but clinical development was ceased due to toxicity concerns. It was approved only in 2003 by the US FDA.

Mechanism of Action

Rapidly bactericidal by apparently inserting into the cytoplasmic membrane of targeted Gram-positive pathogens, where it undergoes structural changes associated with binding of calcium ions, which in turn leads to pore formation, as well as depolarization of the membrane and inhibition of amino acid transport and peptidoglycan formation.^{3,4}

Indications

Primarily active only against Gram positive organisms.

- The treatment of complicated skin and skin-structure infections caused by susceptible strains of the following organisms:
 - *S. aureus* (including methicillin-resistant strains)
 - *Streptococcus pyogenes*
 - *Streptococcus agalactiae*
 - *Streptococcus dysgalactiae* (subspecies *equisimilis*)
 - *Enterococcus faecalis* (vancomycin-susceptible strains only).
- *Staphylococcus aureus* bloodstream infections (including right-sided infective endocarditis).

Daptomycin can be used in combination regimens when infection with a gram-negative or anaerobic organism is either suspected or confirmed. This drug's action is rapidly bactericidal.

Off-label or Investigational Use

Daptomycin is active against VRE.

Utility in Primary Care

This parenteral agent is unlikely to be used widely in primary care practice, although it is one possible alternative for the treatment of patients with resistant, aerobic,

gram-positive pathogens, including MRSA. It is approved only for specific indications at present. Application in the treatment of respiratory tract infections is very limited which is mainly attributed to inactivation of the drug by pulmonary surfactant.⁵ Researchers are considering daptomycin as a possible alternative to vancomycin, linezolid, and the fluoroquinolones for the treatment of MRSA infections. It may also be useful in the treatment of VRE infections, especially if these become more widely disseminated in the community. *Also*, it constitutes an attractive option for the treatment of neutropenic patients, and investigations in this direction are ongoing.⁶ At this time, specialists do not consider it more effective than linezolid or vancomycin.

Although daptomycin is available only for administration via the parenteral route, it is administered once daily, making it possible to deliver it in an ambulatory care setting. Daptomycin is well-tolerated, but it has been associated with myopathy and myositis. While uncommon, these adverse reactions can be severe.

Potential Problems

Dosing more than once a day may lead to elevations of creatine phosphokinase levels. Pseudomembranous colitis is a risk, as it is with all antibacterial agents.

Patients receiving this drug should be assessed for the development of muscle pain or weakness and creatine phosphokinase levels should be determined weekly. Clinicians should be aware that daptomycin has been confused with the similarly named anticancer agent dactinomycin.

Dosage

It is administered @ 4 mg/ kg over a 30 minute period by IV infusion in 0.9 percent sodium chloride injection once every 24 hours for 7 to 14 days. Adults with renal impairment characterized by a creatinine clearance of less than 30 ml/ min (including patients who are undergoing hemodialysis or continuous ambulatory peritoneal dialysis), dose modification is indicated (4 mg/ kg once every 48 hours).

Linezolid

Class

Oxazolidinones; represent a new class of synthetic antibacterials which are unrelated to any currently marketed agent. It was first approved for clinical use by the FDA in 2000.

Mechanism of action

Unique mechanism of bacterial protein synthesis inhibition involving interference with the binding of mRNA to the ribosomes at the initiation phase of translation.⁷ It binds to the 50s subunit of the bacterial ribosome.

Indications

Treatment of patients with:

- Vancomycin-resistant *Enterococcus faecium* infections, with or without concomitant bacteremia
- Nosocomial pneumonia caused by *S. aureus* (methicillin-resistant and -susceptible strains) or *S. pneumoniae* (penicillin-susceptible strains and only some resistant strains)
- Complicated skin and skin-structure infections, including diabetic foot infections without concomitant osteomyelitis caused by *S. aureus* (methicillin-resistant and methicillin-susceptible strains), *S. pyogenes*, or *S. agalactiae*
- Linezolid could be of particular value in the treatment of infections caused by MRSA producing the Panton-Valentine leukocidin (PVL) toxin, which are commonly community-acquired and involve mainly the skin and soft tissues or the lower respiratory tract.⁸
- Uncomplicated skin and skin-structure infections caused by *S. pyogenes* or methicillin-susceptible strains of *S. aureus*
- Community acquired pneumonia (CAP) caused by methicillin-susceptible strains of *S. aureus* or penicillin-susceptible strains of *S. pneumoniae*, including patients with concomitant bacteremia.
- Combination therapy may be required if infection with a gram-negative organism is suspected.
- Also, active against atypical bacteria.

Off-label or Investigational Use

Linezolid has not been tested in patients with decubitus ulcers but could be useful in that situation. As it is available for oral administration, it may be clinically useful in the treatment of infections requiring prolonged antibiotic therapy, such as endocarditis⁹ or osteomyelitis.^{10,11}

Utility in Primary Care

Linezolid is available for oral and parenteral administration, which facilitates the transition from inpatient to outpatient care. This valuable agent is active against gram-positive organisms, as well as VRE and MRSA.^{12,13} The use of linezolid has been restricted at some institutions because the drug has been prescribed as a first-line agent for the treatment of patients with staphylococcal infections when the presence of MRSA was possible, but not confirmed. Linezolid is also considerably more expensive than alternative agents, including vancomycin.

Accumulated evidence from large clinical studies comparing vancomycin and linezolid in patients with MRSA infections has shown little difference in efficacy. Hospital-acquired pneumonia caused by MRSA seems to be an exception, however, with linezolid producing a better outcome and lower mortality than vancomycin.¹⁴ These data

were derived from a subgroup analysis, however, so specialists would like to see the findings replicated elsewhere. For other forms of suspected MRSA infection, vancomycin is still used in most institutions as first-line treatment.

Once MRSA is confirmed and the patient is ready for discharge, therapy can continue with linezolid, with its predictable activity against MRSA. Note, however, that the newer fluoroquinolones with good activity against gram-positive organisms, such as gemifloxacin, moxifloxacin, and gatifloxacin, as well as TMP-SMX, may also be effective alternates for oral therapy and are less expensive than linezolid. The microbiological data are crucial in MRSA infections, however. Use of a fluoroquinolone or TMP-SMX to treat MRSA is not advisable until the antibiotic sensitivities of the organism are confirmed. In most situations, of course, confirmation of MRSA and the sensitivity data become available at the same time. The bottom line is that if the infection is life-threatening, vancomycin or linezolid use is recommended. For skin or soft-tissue infections that can be treated orally another antibiotic may be considered.

Potential Problems

To prevent the development of resistance to linezolid, experts in this field urge clinicians to avoid using it to treat methicillin-sensitive staphylococcal infections or enterococcus infections that are sensitive to other antibiotics. Disturbances of gastrointestinal function (diarrhea, nausea, and vomiting) were the most commonly observed side effects. Severe rashes and lactic acidosis have also been reported in patients taking linezolid. Prolonged administration of linezolid carries an increased risk for the development of specific types of adverse events, such as myelosuppression (primarily thrombocytopenia) or peripheral neuropathy that may not be reversible.^{9,10}

Drug Interaction

Probenecid

Dosage

Children 10 mg/kg q12 h IV or PO, adults 600 mg IV or po, q12 h for 10 to 14 days.

Other Oxazolidinones

Ranbezolid (RBX 7644)

It has been tested on pneumococcal and staphylococcal strains.¹⁵ Activity against pneumococci was similar irrespective of the strains' —lactam, macrolide, or quinolone susceptibilities. The MIC values for coagulase-negative staphylococci were lower than those for *S. aureus*. The compound also showed very good *in vitro* activity against both gram-negative and -positive anaerobes.

Eperezolid- It is active orally or intravenously against multi-drug-resistant, gram-positive bacteria. There is a uniform susceptibility in sensitive bacteria independent of resistance to other antibiotics.

Ertapenem

Class

Carbapenem. It was first approved by the USFDA for clinical use in 2001.

Mechanism of Action

It acts by inhibiting peptidoglycan synthesis. Carbapenems are primarily bactericidal.

Indications

The treatment of adults with one of the following:

- Complicated intra-abdominal infection due to *Escherichia coli*, *Clostridium clostridioforme*, *Eubacterium lentum*, *Peptostreptococcus* species, *Bacteroides fragilis*, *Bacteroides distasonis*, *Bacteroides ovatus*, *Bacteroides thetaiotaomicron*, or *Bacteroides uniformis*.
- Complicated skin and skin-structure infections caused by *S. aureus* (methicillin-susceptible strains only), *S. pyogenes*, *E. coli*, or *Peptococcus* species
- Community-acquired pneumonia (CAP) caused by *S. pneumoniae* (penicillin-susceptible strains only), including cases with concomitant bacteremia, *Haemophilus influenzae* (beta-lactamase-negative strains only), or *Moraxella catarrhalis*
- Complicated urinary tract infections, including pyelonephritis due to *E. coli*, including cases with bacteremia, or *Klebsiella pneumoniae*
- Acute pelvic infections, including postpartum endomyometritis, septic abortion, and postsurgical gynecologic infections caused by *S. agalactiae*, *E. coli*, *B. fragilis*, *Porphyromonas asaccharolytica*, *Pepto-streptococcus* species, or *Prevotella bivia*.

Utility in Primary Care

Ertapenem has a narrower spectrum of activity than other carbapenems, which may be an advantage in some clinical situations. It is not active against *Acinetobacter* or *Pseudomonas* species, but it is very effective against other gram-negative, gram-positive, and anaerobic organisms. Some experts think of ertapenem as a combination of ceftriaxone and metronidazole. It has excellent activity against enteric organisms and is administered once a day. It is an appropriate choice in a situation in which ceftriaxone might otherwise be used, but coverage against anaerobes was also sought—for example, a patient admitted for treatment of pneumonia but at risk of aspiration because a seizure disorder, drug overdose, or alcohol abuse.

Daily dosing makes it convenient for treating patients with pneumonia who reside in long-term care facilities. Ertapenem can be administered parenterally to patients in the emergency department (ED) and then continued at a long-term care facility.¹⁶ High-dose ampicillin/sulbactam might be an alternative in this setting, but it must be administered several times a day.

Very-broad-spectrum antibiotics such as piperacillin/tazobactam, ticarcillin/clavulanate, imipenem, or meropenem are often prescribed for patients with very severe pneumonia. More important, the anti-pseudomonal activity of these drugs is usually unnecessary in this clinical setting and may contribute to resistance among gram-negative organisms.

Potential Problems

It may be prudent to monitor renal function in elderly patients, as ertapenem is excreted largely by the kidney. As with most antibiotics, pseudomembranous colitis has been reported in association with ertapenem use.

Dosage: 1 g either given once daily for up to 7 days IM or up to 14 days IV.

Other Carbapenems

Doripenem

This is a new parenteral carbapenem that has bactericidal activity against many gram-positive and gram-negative aerobic organisms encountered in patients with HAP. It has a broad spectrum of antimicrobial activity, including Gram-negative, Gram-positive and anaerobic bacteria; MRSA and VRE are excluded, however. Doripenem appears to be more active *in vitro* against *P. aeruginosa* than imipenem.¹⁷ Doripenem appears to be equally or slightly more active against *P. aeruginosa* than meropenem.^{18, 19} It was approved by the FDA in 2007 for the treatment of complicated intra-abdominal infections and complicated urinary tract infections, including pyelonephritis. Apart from these indications, doripenem has been favourably compared with piperacillin/tazobactam and imipenem/cilastatin in two multicenter open-label randomized clinical trials in patients with nosocomial pneumonia and ventilator-associated pneumonia, respectively.^{20, 21}

Quinupristin-dalfopristin

Class

Streptogramins. These antibiotics are produced naturally by *Streptomyces* species, but the therapeutic use of the natural compounds is limited. Quinupristin-dalfopristin is a 30:70 combination of a type B and a type A streptogramin.²² It is a water-soluble injectable preparation and was approved by the USFDA in 1999.

Mechanism of Action

The two components target the late and early stages of bacterial protein synthesis, respectively, and thus have a synergistic inhibitory effect. They inhibit bacterial growth by disrupting the translation of mRNA into protein. Individually, the two components are bacteriostatic, but the combination has bactericidal activity against most gram-positive bacteria.

Indications

Active *in vitro* against various pathogens, including MRSA (commonly exhibiting bactericidal activity) and vancomycin-resistant *E. faecium* (commonly exhibiting bacteriostatic activity), but is typically inactive against *E. faecalis*. Currently approved indications are-

- Vancomycin-resistant *E. faecium* infections.
- Complicated skin and skin-structure infections caused by methicillin-susceptible *S. aureus* or *Streptococcus pyogenes*.
- *Quinupristin-dalfopristin is considered to be one of the few potential treatment options for endocarditis caused by isolates of E. faecium that exhibit resistance to vancomycin, penicillin and aminoglycosides.*²³

Utility in Primary Care

Extremely limited. Mainly indicated for use in tertiary care centers for infections by specific organisms that are resistant to multiple antibiotics.

Potential Problems

It has a relatively high rate of reported adverse events with use. Development of phlebitis at the injection site has been reported, which may be avoided by administration via a central line.

Variable numbers of patients have developed myalgias and/or arthralgias that may be severe. These events are more likely to occur in patients with chronic liver disease, in liver transplant recipients, or those receiving cyclosporine or mycophenolate.²⁴ The clinical utility of quinupristin-dalfopristin is further limited by numerous drug interactions: the drug inhibits the cytochrome P450 3A4 isoenzyme and therefore can increase the serum levels of drugs that are metabolized by this enzyme, e.g. astemizole, cisapride, cyclosporine, disopyramide, lidocaine, midazolam, nifedipine, quinidine, and terfenadine.²⁵

Dosage

This drug is administered intravenously at a dose of 7.5 mg/kg every 8 hours.

Tigecycline

Class

Glycylcycline. It is derived by modification of the nine-position of minocycline. Tigecycline was first approved by the USFDA for clinical use in 2005.

Mechanism of Action

These antibiotics are bacteriostatic, and they act by binding to the bacterial 30s ribosomal subunit and by blocking entry of amino-acyl tRNA molecules into the A site of the ribosome. Amino acid residues are prevented from becoming incorporated into elongating peptide chains, which leads to inhibition of protein synthesis.

Indications

It is active against VRE strains and MRSA, as well as certain Enterobacteriaceae and anaerobes.²⁶ Resistance to tigecycline by *P. aeruginosa* and reduced susceptibility among *Proteus* species has been noted. The current indications for use include (each caused by specific pathogens):

- Complicated skin and skin-structure infections
- Complicated intra-abdominal infections
- Community-acquired pneumonia.

Tigecycline may also be active, although not consistently, against a substantial proportion of isolates of multidrug-resistant or carbapenem-resistant *Acinetobacter baumannii*. In this regard it constitutes one of the few potential therapeutic options against carbapenem-resistant *A. baumannii*.²⁷

Utility in Primary Care

It probably has limited use in primary care practice. Clinicians need to prescribe tigecycline appropriately, to avoid the emergence of resistant strains. As a single antimicrobial agent, tigecycline confers broad antibiotic coverage against vancomycin-resistant enterococci, methicillin-resistant *S. aureus*, and many species of multidrug-resistant gram-negative bacteria.

Potential Problems

The main adverse reactions are nausea and vomiting. As with tetracyclines, tigecycline may cause permanent tooth discoloration, so it should not be taken by young children or pregnant women. Drug interactions have not been observed.

Dosage

It is available as an intravenous formulation. An initial loading dose of 100 mg is followed by 50 mg every 12 hours for 7 to 14 days.

Gemifloxacin

Class

Fluoroquinolone. Gemifloxacin was approved in 2003 by the USFDA.

Indications

It has enhanced *in vitro* activity compared with ciprofloxacin against gram-positive pathogens, particularly

S. pneumoniae, including penicillin resistant and multidrug-resistant isolates.²⁸

It has been used for the treatment of acute bacterial exacerbation of chronic bronchitis (AECB) caused by *S. pneumoniae*, *H. influenzae*, *Haemophilus parainfluenzae*, or *M. catarrhalis* and mild-to-moderate CAP caused by *S. pneumoniae* (including multidrug resistant strains of pneumonia [MDRSP]), *H. influenzae*, *M. catarrhalis*, *Mycoplasma pneumoniae*, *Chlamydia pneumoniae*, or *K. pneumoniae*. Note that MDRSP refers to *S. pneumoniae* strains that are resistant to at least 2 of the following drugs or drug classes: penicillin, second-generation cephalosporins, macrolides, tetracyclines, and trimethoprim/ sulfamethoxazole (TMP-SMX).

Off-label or Investigational Use

Gemifloxacin is active against some *Enterobacteriaceae*. In addition, it exhibits *in vitro* minimal inhibitory concentrations (MICs) of 0.25 mcg/ ml or less against at least 90 percent of strains of 2 gram-positive organisms—*S. aureus* and *S. pyogenes*—and several gram-negative ones, including *Legionella pneumophila* and *Proteus vulgaris*. The clinical significance of these *in vitro* data is unclear.

Utility in Primary Care

Gemifloxacin has strong activity against gram-positive bacteria, most importantly *S. pneumoniae* and *S. aureus*, distinguishes it from other fluoroquinolones.^{29,30} Otherwise, its spectrum of activity is quite similar to those of levofloxacin, gatifloxacin, and moxifloxacin. Unlike ofloxacin, levofloxacin, and ciprofloxacin, however, gemifloxacin is not active against mycobacteria. This is not a common use for these drugs, however. Gemifloxacin is not as useful as ciprofloxacin or levofloxacin against *Pseudomonas aeruginosa*, a factor, which may limit its usefulness in patients with cystic fibrosis.

The blood levels of gemifloxacin are lower than those achieved by moxifloxacin and levofloxacin, and its half-life is shorter. Nonetheless, its *in-vitro* anti-pneumococcal activity is excellent and is estimated to be 4 times that of moxifloxacin and 10 to 100 times that of levofloxacin. Whether these *in vitro* differences are clinically important is unclear.

Pneumococcal resistance to levofloxacin has been reported in Canada, and some resistance has been seen in the United States, and treatment failures have also been reported with ciprofloxacin. Gemifloxacin could be a treatment option in this situation. Experts in this field recommend considering gemifloxacin if drug-resistant pneumococcal infection is suspected because of a documented resistant isolate, or because the patient is vulnerable as a result of frequent antibiotic use or recent or frequent hospital stays. Overuse of gemifloxacin could render it less useful, however, so specialists caution against prescribing without a good reason. Also consider that levofloxacin is

inexpensive and well-tolerated. Gemifloxacin is expected to be an excellent choice for patients with CAP and AECB, but it may not be any more effective than some other fluoroquinolones or antibiotics in other classes.

Gemifloxacin may ultimately be extremely useful in patients with MRSA, and a certain percentage of MRSA isolates are sensitive to fluoroquinolones. Until recently, MRSA was not considered a risk in community-acquired infections and nafcillin, for example, could be safely used in a patient with endocarditis and a history of IV drug use. It is no longer safe to make this assumption. Community acquired MRSA infections, especially skin and soft-tissue infections are increasing in prevalence. In fact, infectious disease specialists often recommend that when a patient is hospitalized with a staphylococcal infection, even if it was acquired in the community, that it be treated with an agent that is active against MRSA. Risk factors for MRSA include frequent contact with EDs, hospitals, and frequent use of antibiotics. While this is true nationwide, there are geographic differences in the prevalence of community-acquired MRSA.

Some of the newer fluoroquinolones are active against anaerobes, organisms which are cause for concern among patients with CAP who may have aspirated oropharyngeal secretions. Moxifloxacin has shown good *in vitro* activity against anaerobes, but no studies have demonstrated its clinical efficacy against anaerobic infections. Gemifloxacin is less likely to be useful in this situation.

Potential problems

Overuse of gemifloxacin is a possibility. It is considerably more expensive than levofloxacin, however, which should reduce the amount of over prescribing. Side effects may include diarrhea, rash, and nausea. The incidence of rash is 2.8 percent but ranges from 1 to 32 percent, so this drug should not be considered for first-line treatment. As with many fluoroquinolones, there can be prolongation of the QTc interval.

Dosage

AECB- 320 mg/d for 5 days; CAP- 320 mg/ d for 7 days.

Telithromycin

Class

Ketolides. They are semisynthetic derivatives of macrolides.³¹ It was first approved by the USFDA in 2004.

Mechanism of Action

Telithromycin has the ability to bind to the bacterial ribosome more tightly than erythromycin; this is attributed to binding of telithromycin not only to domain V of the 23s rRNA (the binding site for macrolides), but also to domain II.

Indications

As telithromycin binds to an additional site on the bacterial ribosome it is active in vitro against erythromycin-resistant and multidrug resistant isolates of *S. pneumoniae*.³² It is also active against other common respiratory pathogens.³¹ Telithromycin has very good oral bioavailability and a favorable pharmacokinetic profile in respiratory tract infections.³³ Initial approval was given for clinical use in community-acquired pneumonia, acute bacterial exacerbation of chronic bronchitis, and acute bacterial sinusitis. However, following postmarketing surveillance reports of rare but severe adverse events, particularly of hepatotoxicity, the latter two indications were retracted.³³

Utility in Primary Care

Ketolides are the latest structural derivatives of erythromycin to be added to the macrolide family. This oral agent was developed to help manage the problem of macrolide-resistance in the pneumococcus and multidrug-resistant gram-positive bacteria in general, and it may become a first-line agent for that purpose in certain geographical areas, where pneumococcal resistance to macrolides has reached significant levels. Telithromycin is active against *S. pneumoniae*, *H. influenzae*, *M. catarrhalis*, and *S. pyogenes*. In addition, it is active against some atypical respiratory pathogens, including *C. pneumoniae*, *L. pneumophila*, and *M. pneumoniae*.³⁴

Telithromycin can be taken without regard for meals and requires no dosage reduction in elderly patients or those with hepatic impairment. It is well absorbed after oral administration and achieves rapid penetration into respiratory tissues and fluids.

Potential Problems

The most common adverse effects associated with telithromycin include diarrhea, nausea, headache, and dizziness. Prolongation of the QTc interval is a possibility and the drug interacts with ketoconazole and itraconazole and is a statin inhibitor. Scattered but severe adverse events, especially hepatotoxicity warrant careful use of this drug, and only in approved indications.

Dosage

800 mg once daily for 5 to 10 days.

Glycopeptides and Derivatives

New glycopeptide derivatives undergoing clinical development include oritavancin (a derivative of the glycopeptide chloroeremomycin), as well as the lipoglycopeptides dalbavancin and telavancin (derivatives of teicoplanin and vancomycin, respectively).

Oritavancin

It has potent bactericidal activity against MRSA and VRE,³⁵ and has mainly been evaluated in clinical trials for the treatment of complicated skin and skin-structure infections.³⁶ In addition to inhibiting peptidoglycan synthesis, a second recently identified mechanism, involves the rapid disruption of both membrane potential and permeability. These combined activities provide oritavancin with potent activity against a wide spectrum of gram-positive organisms. Oritavancin demonstrates activity against both MSSA and MRSA.³⁷ Importantly, oritavancin possesses activity against VISA and VRSA isolates.³⁸

In vitro it has been noted to cause alterations in animal lysosome activity suggesting oritavancin has the potential to cause a mixed-lipid storage disorder; however, the clinical significance to humans is unknown.³⁹ Other adverse effects reported include transient elevations in hepatic transaminases and injection site reactions.

Dalbavancin

It is a lipoglycopeptide. Dalbavancin binds to the terminal D-alanyl-D-alanine of the pentapeptide chain, which inhibits peptidoglycan cross-linking and leads to cell death. It is active solely against Gram positive organisms.

Dalbavancin exhibits bactericidal activity against pneumococci, regardless of penicillin sensitivity.⁴⁰ It has slow bactericidal activity against *S. aureus*, both methicillin-sensitive and -resistant.⁴¹

This drug is active in vitro against MRSA; however, similarly to teicoplanin, it is not active against vancomycin-resistant *E. faecium* with the van A genotype.⁴² It has a prolonged serum elimination half-life that allows for a dosing interval of 1 week, thereby rendering this agent an appealing option for outpatient parenteral antimicrobial therapy. It has mainly been evaluated in clinical trials for the treatment of complicated skin and skin-structure infections and catheter-related bacteremia.^{43, 44}

Approximately one third of dalbavancin is excreted unchanged in the urine, suggesting non-renal routes of elimination. No dosage adjustment is required for patients with mild to moderate renal impairment. The most commonly reported adverse events included pyrexia, headache, and gastrointestinal symptoms. No auditory or vestibular toxicity, or “red man” syndrome was observed in study subjects. Dalbavancin has been shown to be devoid of major ecologic effects on normal intestinal microflora.⁴⁵

Telavancin

This drug is also an investigational lipoglycopeptide. It inhibits cell wall synthesis by binding to peptidoglycan precursors containing the terminal D-ala-D-ala residue and preventing cross-linking. It is active and bactericidal against

MRSA and has greater activity than clinically available glycopeptides against VRE, particularly against those carrying the vanB genotype.⁴⁶ It has mainly been evaluated clinically for the treatment of patients with complicated skin and skin-structure infections and nosocomial pneumonia.^{47,48}

The primary elimination route is renal, and the elimination half-life is 8 to 9 hours. It is anticipated that patients with moderate to severe renal dysfunction will require dosage adjustments. Reported adverse events from clinical trials include taste disturbances, nausea, headache, and insomnia.

Iclaprim

Class

A synthetic diaminopyrimidine, a racemic mixture of two equipotent enantiomers.

Mechanism of action

It is a selective inhibitor of the enzyme dihydrofolate reductase (DHFR), similar to trimethoprim. Iclaprim prevents the production of tetrahydrofolic acid by interrupting the bacterial biosynthetic pathway.⁴⁹ As a specific and selective DHFR inhibitor, iclaprim preferentially prevents the synthesis of bacterial DNA and RNA.⁵⁰ Currently being developed as monotherapy in view of its potent intrinsic activity.⁵¹

Indications

Iclaprim has *in vitro* activity against *S. aureus*, including MRSA, and a single VRSA strain.^{52,53} Against penicillin-sensitive and penicillin-resistant pneumococci, it demonstrates more potent activity than trimethoprim.^{54,55} Iclaprim is also active against trimethoprim-resistant staphylococci and pneumococci.⁵⁵ Iclaprim is active against the respiratory pathogens *H. influenzae* and *Moraxella catarrhalis*. Unlike trimethoprim, it exhibits activity against the intracellular pathogen *C. pneumoniae*.⁵⁶ In addition, this drug is active against the atypical pathogen *Legionella pneumophila*.⁵⁷ The activity of iclaprim against Enterobacteriaceae is generally comparable to trimethoprim.⁵⁸

- Data suggest iclaprim achieves the necessary respiratory concentrations to be efficacious for the treatment of pneumonia.
- Early preclinical data suggest iclaprim may have a role in the treatment of HAP due to gram-positive pathogens, and clinical trials are under way.
- May also have a role in the therapy of complicated skin and skin-structure infections (cSSSI).

An oral formulation is also under trial and this makes iclaprim an attractive option for an IV to PO switch.

NEWER CEPHALOSPORINS

Cefditoren

Cefditoren is a newer third-generation cephalosporin that is available for oral administration. It was approved by the USFDA in 2001, and is currently indicated for use in patients with various types of respiratory tract infections (CAP, acute bacterial exacerbation of chronic bronchitis, and pharyngitis/tonsillitis) and uncomplicated SSSI. Cefditoren appears more active *in vitro* than other third-generation oral cephalosporins against penicillin-non-susceptible *S. pneumoniae*.^{59, 60}

Ceftobiprole

Ceftobiprole is an investigational “fifth”-generation cephalosporin with a broad spectrum of activity encompassing both gram-positive and gram-negative organisms. Like other β -lactam antibiotics, ceftobiprole prevents cell wall formation by binding to and inhibiting penicillin binding protein (PBPs). Due to specific changes brought about by structural engineering its structure ceftobiprole has bactericidal activity against methicillin-sensitive and -resistant *S. aureus*.⁶¹ Ceftobiprole is also active *in vitro* against VISA and VRSA.⁶² The strong binding affinity of ceftobiprole to PBP-2x provides enhanced activity against penicillin sensitive and -resistant *S. pneumoniae* and other streptococci.⁶³

Ceftobiprole generally exhibits potent activity against Enterobacteriaceae with the exception of *Proteus vulgaris*.⁶¹ The anti-pseudomonal activity of ceftobiprole is similar to cefepime. Like other cephalosporins, ceftobiprole is inactive against ESBL-producing isolates.⁶⁴ Ceftobiprole also lacks activity against many nonfermentative gram-negative bacilli, including *Acinetobacter* spp., *Burkholderia cepacia*, and *Stenotrophomonas maltophilia*.⁶⁵

This drug has recently completed phase III trials for treatment of cSSSIs, CAP and HAP (including VAP).

Ceftobiprole was generally safe and well tolerated in clinical studies. Frequently reported adverse effects included taste disturbances, nausea, and vomiting. Ceftobiprole is predominantly excreted unchanged in the urine, has an elimination $t_{1/2}$ of 3 to 4 hours, and requires dosage adjustment for renal impairment.⁶⁶

Ceftaroline

Ceftaroline is another broad-spectrum cephalosporin with activity against MRSA. Like ceftobiprole, ceftaroline inhibits bacterial cell wall synthesis and has enhanced binding affinity for PBP-2a resulting in anti-MRSA activity. Ceftaroline possesses potent bactericidal activity against many staphylococci, including both MSSA and MRSA.^{67,68} In addition, ceftaroline retains activity against VISA. It is active against *S. pneumoniae*, including penicillin-intermediate and -resistant strains.⁶⁷

Ceftaroline is active against many common gram negative respiratory pathogens, including *H. influenzae*, *E. coli*, *Salmonella spp.*, *Citrobacter freundii*, *Morganella morganii*, *Proteus mirabilis*, and *Klebsiella pneumoniae*.^{67, 68} Importantly, ceftaroline does not possess activity against *P. aeruginosa* and exhibits reduced activity against *E. cloacae*, *P. vulgaris*, and *Providencia spp* compared with ceftobiprole.⁶⁷

Phase III studies for the treatment of community-acquired pneumonia and cSSSIs are currently under way. It may have a role as monotherapy in serious CAP or HAP infections where MRSA is a potential etiologic organism.

The major route of elimination is renal excretion. In patients with mild renal impairment, no dose adjustment is necessary.

12 Steps to Prevent Antimicrobial Resistance in Hospitalized Patients

Prolonging the usefulness of new and older antibiotics should be a prime goal of every health care provider. Many antibiotic resistance problems originate in hospitals and other health care facilities. The CDC offers the following 12 steps as a means of preventing the development of resistance in hospitalized patients. Most of these points have application in office practice, as well.

PREVENT INFECTION

Step 1: Vaccinate

- Give influenza and pneumococcal vaccines to at-risk patients before discharge
- Get your own influenza vaccine every year.

Step 2: Get the Catheters Out

- Use catheters only when essential
- Use the correct catheter
- Use proper insertion and catheter-care protocols
- Remove catheters when they are no longer essential.

DIAGNOSE AND TREAT INFECTION EFFECTIVELY

Step 3: Target the Pathogen

- *Culture the patient.*
- Target empiric therapy to likely pathogens and local antibiogram.
- Target definitive therapy to known pathogens and antimicrobial susceptibility test results.

Step 4: Access the Experts

- Consult infectious diseases experts for patients with serious infections.

USE ANTIMICROBIALS WISELY

Step 5: Practice Antimicrobial Control

- Engage in local antimicrobial control efforts.

Step 6: Use Local Data

- Know your antibiogram
- Know your patient population.

Step 7: Treat Infection, not Contamination

- Use proper antisepsis for blood and other cultures
- Culture the blood, not the skin or catheter hub
- Use proper methods to obtain and process all cultures.

Step 8: Treat Infection, Not Colonization

- Treat pneumonia, not the tracheal aspirate
- Treat bacteremia, not the catheter tip or hub
- Treat urinary tract infection, not the indwelling catheter.

Step 9: Know When to say No

- Treat infection, not contaminants or colonization
- Fever in a patient with an intravenous catheter is not a routine indication for vancomycin.

Step 10: Stop Antimicrobial Treatment

- When infection is cured
- When cultures are negative and infection is unlikely
- When infection is not diagnosed.

PREVENT TRANSMISSION

Step 11: Isolate the Pathogen

- Use standard infection control precautions
- Contain infectious body fluids (follow air-borne, droplet, and contact precautions)
- When in doubt, consult infection-control experts.

Step 12: Break the Chain of Contagion

- Stay home when you are sick
- Keep your hands clean
- Set an example.

Newer Antiviral Agents

Sameer Guliani, Amita Kaul, SP Yadav, Anupam Sachdeva

INTRODUCTION

Chemotherapy using antiviral agents has a long history, but it has been only recently that a large number of effective antiviral agents have been available. Many early antiviral agents were associated with serious side effects. This is because viral infection of a cell is dependent upon intimate relationship between virus and host cell replication machinery, so that using antiviral agents to target particular viral replication functions also causes changes in normal cellular functions, which the virus has used for its own growth. With further progress in virology, molecular biology and clinical nature of viral infections a more targeted approach can be developed.

Advances in antiviral drug development and in rapid diagnostic methods like shell vial cultures, polymerase chain reactions, antigen detection assays have lead to effective management strategies, particularly for infections due to herpes simplex virus, varicella zoster virus, cytomegalovirus, Influenzae A and B and chronic hepatitis B and C. Moreover, rapid diagnostic tests permitted the introduction of a new preventive strategy termed as preemptive treatment which consists of initiating antiviral treatment only after documenting viral infection to prevent disease due to that virus.

Human Herpes Virus Group

Human herpes viruses are among the most frequent causes of viral disease. Following primary infection, the virus remains latent and reactivates intermittently especially during periods of profound immunosuppression. Treatment strategies have been established for infections due to herpes simplex virus^{1,2} cytomegalovirus and varicella-zoster virus.

Acyclovir

One of the most commonly used antiviral drugs, it is primarily used for the treatment of herpes simplex virus infections, as well as in the treatment of varicella-zoster (chickenpox) and herpes zoster (shingles). It is a synthetic analog of 2-deoxyguanosine and must be activated to its active form by phosphorylation, which takes place intracellularly. It is commonly marketed as tablets (200 mg, 400 mg, 800 mg and 1 gram), topical cream (5%), intravenous injection (25 mg/ml) and ophthalmic ointment (3%).

Valaciclovir and Famciclovir

Both Valaciclovir and Famciclovir are oral drugs.

Valaciclovir is the L-valyl ester of acyclovir, and is rapidly converted to acyclovir after oral administration.¹ The bioavailability of valaciclovir is 3 to 5 times greater than that of oral acyclovir.^{1,2} Famciclovir has a bioavailability of 77 percent, and is an oral prodrug of penciclovir, which has a similar antiviral spectrum to acyclovir.³⁻⁵ Penciclovir is a nucleoside deoxyguanosine analog that inhibits the DNA synthesis of herpes viruses. Because it is very poorly absorbed orally, famciclovir was developed to orally treat herpes virus infections. Penciclovir enters all the cells of the body, both virus-infected and uninfected cells. In the virus-infected cells only, penciclovir is phosphorylated to its active form first by the viral thymidine kinase, which adds the first phosphate and then by a cellular enzyme, which completes the activation. In this way, penciclovir in its active triphosphate state is confined to the virus-infected cells. Once formed, penciclovir triphosphate has a very long intracellular half-life when compared with acyclovir triphosphate. Penciclovir triphosphate is now free to insert in the viral DNA as it is being formed in place of

the nucleotide guanine and terminate the sequence, thus inhibiting replication of the virus. It is not recommended for children under 18 years of age, pregnant or nursing mothers, and its effects have not been studied in immunocompromised patients (although intravenous penciclovir produced no harmful effects). Side effects of intravenous penciclovir (seen in comparable rates in placebo) may be headache, abdominal pain, increased serum lipase, nausea, dyspepsia, dizziness, and hyperbilirubinemia.⁶

The advantage of valaciclovir and famciclovir over acyclovir is their high oral bioavailability, which permits less frequent dosing when treating HSV or VZV disease.^{7,8} These drugs were shown to be well-tolerated and safe in large populations of patients.⁹

Ganciclovir

Ganciclovir has antiviral activity against all members of the human herpes virus group, but is considerably more potent than acyclovir or penciclovir against CMV.¹⁰ Ganciclovir requires intracellular phosphorylation for activation. Conversion to ganciclovir monophosphate is catalyzed by an UL97-encoded phosphotransferase of CMV. Ganciclovir-triphosphate blocks CMV replication by inhibiting the viral DNA polymerase and by being incorporated into the DNA chain, thereby reducing the rate of DNA chain elongation.¹⁰ Ganciclovir is hematotoxic, and thus requires dose reduction or discontinuation of treatment in up to one-third of immunodeficient patients.¹⁰ The oral bioavailability of <10 percent makes intravenous administration of ganciclovir necessary for most indications.¹⁰ An alternative approach is the use of an intraocular sustained-release ganciclovir implant combined with oral ganciclovir, which delays progression of retinitis and reduces the incidence of new CMV disease by about 40 percent over 1 year compared to the implant alone.¹¹

Valganciclovir

Valganciclovir is a monoethyl ester prodrug that, when administered orally, is rapidly hydrolyzed to the active compound ganciclovir. The absolute bioavailability of ganciclovir from valganciclovir is 60 percent.¹² The serum levels of ganciclovir achieved with valganciclovir use are four-fold higher than those with oral ganciclovir because of valganciclovir's superior oral bioavailability. Because the hematologic side effects of ganciclovir are in part dose-dependent and the drug is renally excreted, doses of valganciclovir and both forms of ganciclovir must be reduced in patients with renal dysfunction. Valganciclovir was approved by the US Food and Drug Administration (FDA) for a single indication: treatment of CMV retinitis in patients with acquired immunodeficiency syndrome. Although retinitis is the official indication, the drug is used to treat CMV infections at all sites.¹³

Cidofovir

Cidofovir is a nucleotide analog (nucleoside phosphonate) and is therefore independent from virus-encoded enzymes for activation.²⁹ Cellular enzymes mediate phosphorylation of cidofovir to its active metabolite that selectively inhibits viral DNA polymerase. The long half-life of the active metabolite permits infrequent administration of cidofovir, which needs to be given intravenously because of poor oral bioavailability (<5%).¹⁴ Cidofovir shows potent *in vitro* and *in vivo* activity against CMV and other herpes viruses, and against adenovirus and papilloma virus. The substantial nephrotoxic potential of cidofovir can be lowered by concomitant hydration and administration of probenecid.

Maribavir

1263W94 [maribavir; 5,6-dichloro-2-(isopropylamino)-1, beta-L-ribofuranosyl-1-H-benzimidazole], a novel benzimidazole compound, had been demonstrated to potently and selectively inhibit human cytomegalovirus replication *in vitro* and to have favorable safety profiles in animal species. The mechanism by which maribavir inhibits HCMV replication is by inhibition of an HCMV encoded protein kinase enzyme called UL97 or pUL97.

Maribavir showed promise in Phase II clinical trials and was granted fast track status, but failed to meet study goals in a Phase III trial.¹⁵

Bay 38-4766

The nonnucleosidic BAY 38-4766 was identified as a highly selective inhibitor of human cytomegalovirus (HCMV). The compound selectively inhibits not only HCMV strains, including ganciclovir-resistant, ganciclovir/foscarnet and ganciclovir/cidofovir double-resistant clinical isolates, but also a number of monkey and rodent cytomegaloviruses. In a murine cytomegalovirus (MCMV) pathogenicity model in mice, antiviral efficacy and excellent tolerability were demonstrated. BAY 38-4766-resistant HCMV and MCMV strains are not cross-resistant to the nucleoside analogs ganciclovir and cidofovir or the pyrophosphate analog foscarnet, indicating a different mode of action. Mechanistic studies demonstrated that the high selectivity of this drug class is most likely due to the inhibition of a late stage of the viral replication cycle. Sequence analyses of resistant HCMV and MCMV strains revealed mutations in UL89 and UL104, proteins known to be involved in viral DNA cleavage and packaging. Consequently, the drug is highly specific for the viral as opposed to cellular functions, since UL89 is related to a bacteriophage terminase and no human equivalent exists. In addition, because some of the genes of the viral DNA cleavage and packaging complex are highly conserved among herpes viruses, development of broad-spectrum agents covering

additional human herpes viruses might be possible using this approach.¹⁶

Hepatitis B and C Viruses

Interferon-alpha IFN- α is a lymphokine produced by B-lymphocytes and monocytes, and has antiviral activities that result in decreased viral load and immunomodulatory effects, which assist eradication of virus.¹⁷ IFN- α can be administered subcutaneously or intramuscularly. After initial doses, fever, chills, myalgias, fatigue, nausea, and vomiting may occur, but these symptoms typically improve with subsequent injections and are dose-related.¹⁷ Transient bone marrow suppression may be observed during the first weeks of therapy, and requires close monitoring of blood counts.

Lamivudine

Lamivudine is an oral nucleoside analog, which requires intracellular phosphorylation for activation. The active triphosphate derivative blocks virus replication by terminating the nascent proviral DNA chain, and by interfering with the reverse-transcriptase activity of hepatitis B virus and HIV. The oral bioavailability of 80 percent and the long intracellular half-life permit once daily dosing for therapy of chronic hepatitis B.¹⁸ The incidence of adverse events in patients treated for chronic hepatitis B is similar between lamivudine and placebo.¹⁹

Ribavirin

Ribavirin has antiviral properties against a broad-spectrum of DNA and RNA viruses, and requires activation by intracellular phosphorylation. Ribavirin monophosphate interferes with the synthesis of guanosine triphosphate and thus nucleic acid synthesis, and ribavirin triphosphate inhibits the capping of viral messenger RNA and specifically influenza transcriptase activity. The drug is used in aerosolized form for treatment of respiratory syncytial virus infection in children and immunocompromised hosts, and an oral formulation has beneficial effects in the therapy of chronic hepatitis C.²⁰ Oral ribavirin is generally well-tolerated, and infrequent side effects include hemolysis, anxiety, irritability, fatigue, chronic upper respiratory symptoms, and pruritus.

Chronic Hepatitis B

Until recently, IFN- α was the only approved therapy of chronic hepatitis B. Predictors for a good response to IFN- α treatment are aminotransferase levels >100 IU/ml, the presence of HBV DNA in serum but at a level <200 pg/ml, detectable serum hepatitis B e antigen (HBeAg), a liver biopsy with moderate to severe inflammatory activity, and compensated liver disease.²⁰ With a standard 4-month course of IFN- α , one-third of patients have a virologic

response as compared to 12 percent of untreated controls, and only 5 to 10 percent of those with a seroconversion have reactivation of infection within the next 10 years.²⁰

Oral lamivudine may be used as alternative to IFN- α for therapy of chronic hepatitis B. In a randomized trial, a 1 year-treatment with oral lamivudine at a dose of 100 mg once daily was superior to placebo with regard to seroconversion (16 vs 4%; defined as loss of HBeAg, development of antibody to HBeAg, and undetectable HBV DNA), of sustained normalization of alanine aminotransferase levels (72% vs 24%), and of patients with improved hepatic necroinflammatory activity/ (56% vs 25%).¹⁸ The optimal duration of lamivudine therapy and the effects of combined lamivudine plus IFN- α for treatment of chronic hepatitis B require further study. Moreover, the clinical importance of HBV mutants that emerge during lamivudine therapy needs to be determined.¹⁸

Other Drugs

Adefovir

Adefovir is an acyclic analog of deoxyadenosine monophosphate (dAMP), which has just been approved by the Food and Drug Administration (FDA) for use in chronic hepatitis B. Adefovir has been shown to inhibit the amplification of cccDNA although the *de novo* formation of cccDNA cannot be prevented in duck HBV-infected hepatocytes. In Phase I/II studies, treatment with adefovir results in significant reduction of HBV DNA within 1 to 2 weeks. In a Phase III placebo-controlled trial, adefovir 10 mg daily given for 48 weeks in 171 patients was associated with significantly better histological improvement, a higher rate of HBeAg seroconversion, a three logarithmic reduction of HBV DNA levels and a higher chance of normalization of ALT levels when compared with 167 patients receiving placebo.²¹ Importantly, adefovir is also active against lamivudine-resistant YMDD mutants. Severe renal toxicity has been observed in patients receiving higher doses (60–120 mg daily) of adefovir in trials for patients infected with human immunodeficiency virus (HIV). The renal toxicity is mediated through the human renal organic anion transporter 1 (hOAT1) and may result in proximal renal tubular dysfunction. To date, no clinical renal toxicity has been observed with the 10 mg daily dose.

Tenofovir Disoproxil Fumarate

Tenofovir disoproxil fumarate another acyclic nucleoside analog similar to adefovir, has been approved for the treatment of HIV. *In vitro* studies show that this drug is also effective in suppressing replication of lamivudine-resistant HBV.²² In HIV patients coinfecting with lamivudine-resistant HBV, it causes HBV DNA reduction by 4.5 log. However, to date, no studies have been reported in patients with HBV infection alone.

Entecavir

Entecavir is a carbocyclic deoxyguanosine analog. It is highly effective in inhibiting the priming of the HBV polymerase by guanosine triphosphate during the initiation of HBV replication. Entecavir has been shown to reduce the viral antigens and DNA levels in liver samples of HBV infected woodchucks. The Food and Drug Administration (FDA) has announced the approval of entecavir (Baraclude) tablets and oral solution for the treatment of chronic hepatitis B in adults.

The major adverse events associated with the use of entecavir include severe, acute exacerbation of hepatitis B after discontinuation of entecavir; headache, abdominal pain, diarrhea, fatigue, and dizziness. Entecavir is also effective against lamivudine-resistant HBV although a higher dose of 1 mg daily may be required.

*β -L-2'-Deoxythymidine (Telbivudine)*²³

β -L-2'-Deoxythymidine is one of three L-nucleosides that specifically inhibit HBV replication. The other two members are β -L-2'-deoxycytidine and β -L-2'-deoxyadenosine. The anti-HBV activities are conferred by the common hydroxyl group in the 3'-position of the β -L-2'-deoxyribose sugar of the molecules. Eight logarithmic reduction of viral DNA levels has been demonstrated in the woodchuck model with β -L-2'-deoxythymidine. In Phase I/II clinical trials, β -L-2'-deoxythymidine shows marked dose-proportional antiviral activities with 4 weeks of the 800 mg daily dose causing a 4 log reduction in median HBV DNA levels. No side effects have been observed. The lack of side effects may be related to the L-configuration of the molecule. Clinical trials have shown it to be significantly more effective than lamivudine or adefovir, and less likely to cause resistance.

Chronic Hepatitis C

Therapy of chronic hepatitis C is recommended for patients who have detectable HCV RNA in serum, elevated serum aminotransferase levels, and chronic hepatitis on liver biopsy. Factors predicting a favorable response to treatment with IFN- α include low HCV RNA serum levels, viral genotypes 2 or 3 (by contrast to genotype 1), the absence of cirrhosis, low hepatic iron stores, short duration of liver disease, and younger patient age.²⁴ However, IFN- α monotherapy for up to 48 weeks results in sustained virologic response (defined as undetectable HCV RNA levels in serum 24 weeks after the end of therapy) in <20 percent of patients. Several recent randomized studies comparing the combination of pegylated IFN- α and oral ribavirin to IFN- α alone for a treatment duration of 24 or 48 weeks showed higher rates of sustained virologic response (up to 70%) with the combination therapy, both for patients who received initial treatment and for those who relapsed after initial response to therapy.²⁵ Moreover, combination

therapy administered for 48 weeks was more effective than when given for only 24 weeks.²⁵ Peg interferon alpha-2a and Ribavirin are now being used for children with benefit. Other protease compounds (for hepatitis C) in development include TMC-435, vaniprevir, BI-201335, BMS-650032, and danoprevir. For more details see the Chapter on Hepatitis C.

Influenza Viruses

Influenza A and B viruses are responsible for seasonal epidemics that cause significant morbidity in the general population, and mortality in elderly and immunocompromised patients. Antiviral drug treatment of influenza can be done with amantadine and rimantadine. Both amantadine and rimantadine have an antiviral activity that is restricted to influenza A virus. These agents (M2 inhibitors) are amines that inhibit viral replication by targeting the M2 surface protein of the virus, thereby interfering with the uncoating process.²⁶ In Europe, only amantadine is licensed. Treatment with both drugs is associated with neurological and gastrointestinal side effects, and with the rapid emergence of virus resistance, which limits their usefulness.²⁶

Neuraminidase Inhibitors

The neuraminidase of influenza viruses plays an essential role in allowing virus release from the surface of infected cells by cleaving sialic acid residues of the cell membrane. The active site of the neuraminidase is highly conserved among both influenza A and B strains. Neuraminidase inhibitors have been developed that block the interaction of this enzyme with the sialic acid residues by fitting into the shallow pocket of the neuraminidase active site.

Zanamivir (GG167)

Zanamivir is a potent inhibitor of the neuraminidase of both influenza A and B viruses.²⁷ Because of its low oral bioavailability (about 2%), this drug is used topically. Among patients who were treated within 48 hours of onset of influenza-like disease and who had laboratory-confirmed influenza virus infection, inhaled zanamivir reduced the median time to alleviation of major influenza symptoms by 1 day compared to placebo.²⁷ In patients who began treatment within 30 hours of disease onset, median time to resolution of influenza symptoms was shortened by 3 days.²⁷ Similar results were obtained in another randomized comparison of inhaled zanamivir versus placebo. Of note, the proportion of patients with influenza-like symptoms who had laboratory-confirmed influenza in the two studies was 63 and 71 percent, respectively, and the majority of these infections were due to influenza A virus (56 and 67%, respectively). Topical zanamivir in both trials was well tolerated, including among patients with asthma.²⁷

Oseltamivir (GS4104)

Oseltamivir (Tamiflu) is the oral prodrug of compound GS 4071, which inhibits influenza A and B virus neuraminidase.²⁸ After oral administration, this prodrug is rapidly converted to GS4071, which has a half-life of approximately 8 hours that permits twice daily dosing.²⁸ When therapy was initiated within 36 hours of febrile respiratory illness, a 5-day course of oseltamivir resulted in shortening of disease duration in influenza virus-infected patients by 30 percent compared to placebo, and this effect was similar whether twice daily doses of 75 or 150 mg were used. If therapy was initiated within 24 hours of symptom onset, the duration of the illness was reduced by 40 percent. Recent data suggest that neuraminidase inhibitors may also have a role in the prevention of influenza among healthy adults and in the postexposure prophylaxis among household contact.²⁹ Moreover, issues under study with neuraminidase inhibitors are the determination of their therapeutic and prophylactic efficacy against influenza viruses in high-risk populations. The emergence of antiviral resistance to these agents, although rare, was described, and requires careful surveillance. Of concern, only about two-thirds of infections among patients with febrile respiratory disease during the influenza season are due to influenza viruses, which suggest that one-third of patients may be erroneously treated with neuraminidase inhibitors if rapid diagnosis cannot be made. Rapid and sensitive detection assays for influenza viruses that can be performed by primary care physicians or the patients themselves are needed for the judicious use of these new anti-influenza drugs. As of December 2010, the World Health Organization (WHO) reported 314 samples of the prevalent 2009 pandemic H1N1 flu tested worldwide have shown resistance to oseltamivir.

Laninamivir (CS-8958)

It is a neuraminidase inhibitor which is being researched for the treatment and prophylaxis of influenza virus A and influenza virus B. It is currently in phase III trials.

Advances in understanding the mechanisms involved in influenza virus replication have revealed a number of potential targets that might be exploited in the development of new agents. Among these agents are T-705 (Favipiravir), a polymerase inhibitor, and DAS181, an attachment inhibitor.

T-705 (favipiravir; 6-fluoro-3-hydroxy-2-pyrazinecarboxamide) has antiviral activity against seasonal influenza viruses and a mouse-adapted H5N1 influenza virus derived from a benign duck virus. However, its efficacy against highly pathogenic H5N1 viruses, which are substantially more virulent, remains unclear.

DAS181 is an investigational antiviral medication with preclinical activity and against parainfluenza and influenza viruses. The receptor for both parainfluenza and

influenza on airway epithelial cells is sialic acid. DAS181, a recombinant sialidase fusion protein, removes sialic acid residues from airway epithelium, thereby preventing both the initial step in PIV and IFV infection and the spread of existing infection. DAS181 is currently being studied in a Phase II clinical trial.

SUMMARY

A lot of newer antiviral agents are being developed to meet the demand especially to tackle the emergence of viral infections in immunosuppressed host and emerging resistance to older drugs. They have better bioavailability, lesser side effects and better tolerated. Further studies are required to document their efficacy in pediatric age group.

Newer Antifungal Agents: A Promising Road Ahead

Himani Manchanda, SP Yadav, Anupam Sachdeva

The number of agents available to treat fungal infections has increased by 30 percent since the year 2000, yet still only 15 agents are currently approved for clinical use. The greater number of medications now available allows for therapeutic choices; however, differences in antifungal spectrum of activity, bioavailability, formulation, drug interactions, and side effects necessitates a detailed knowledge of each drug class.

POLYENES

Amphotericin B (AMB) and nystatin are the currently available polyenes, although differing safety profiles have limited nystatin to topical use.¹ The polyenes bind to ergosterol present within the fungal cell wall membrane. This process disrupts cell wall permeability by forming oligodendromes functioning as pores with the subsequent efflux of potassium and intracellular molecules causing fungal death.² There is also evidence that AMB acts as a proinflammatory agent and further serves to stimulate innate host immunity. This process involves the interaction of AMB with toll-like receptor 2 (TLR-2), the CD14 receptor, and by stimulating the release of cytokines, chemokines, and other immunologic mediators. It has been suggested that AMB may interact with host humoral immunity after the observation of synergistic activity of AMB and antibodies directed at heat shock protein 90 (hsp90), although further confirmatory data are needed.²

When AMB resistance occurs, it is generally attributed to reductions in ergosterol biosynthesis or the synthesis of alternative sterols with a reduced affinity for AMB. Resistance to AMB is common in *Aspergillus terreus*, *Scedosporium apiospermum*, *Scedosporium prolificans*, *Trichosporon* spp, and *Candida lusitanae* (Table 1). Resistance has been reported with several other species.³

The peak serum level to mean inhibitory concentration (MIC) ratio is the best pharmacologic predictor of

outcomes with polyene therapy. Drug levels are infrequently measured, nor are they necessary, and they are typically available only in the research setting.⁴

AMB is primarily used intravenously (IV) or through the inhalational route. In attempts to avoid the nephrotoxicity seen with amphotericin B deoxycholate (AmBd; Fungizone) several other formulations have been developed. The lipid preparations include: liposomal amphotericin B (L-AMB; Ambisome), amphotericin B lipid complex, (ABLC; Abelcet), and amphotericin B colloidal dispersion (ABCD; Amphotec, Amphocil). All currently available formulations are highly protein bound (>95%, primarily to albumin) and have long half-lives. AMB exhibits poor cerebrospinal fluid levels (<5% of concurrent serum concentration); however, this agent remains the treatment of choice for cryptococcal meningitis.⁵ Previous reports have described the use of intrathecal AMB in an attempt to circumvent the poor cerebrospinal fluid (CSF) penetration; however, this practice is seldom used because of the difficulty of administration, poor patient tolerability, and availability of alternative agents for use in the salvage setting of invasive mycoses. AMB also has low vitreous penetration (0–38%) and intraocular injections may be required to achieve appropriate levels during therapy of deep ophthalmologic fungal infections, including candidal endophthalmitis.^{6,7} The exact route of elimination of AMB is not known and despite the well-known nephrotoxicity, dosing need not be adjusted in patients who have a decreased glomerular filtration rate.

The broad antifungal spectrum and experience with the use of amphotericin B accounts for its continued use despite toxicity concerns. Liposomal amphotericin B remains the recommended antifungal during the treatment of neutropenic fever after an open-label, randomized international trial comparing L-AMB to voriconazole. Although fewer breakthrough infections (including those caused by *Aspergillus* spp.) occurred in patients receiving

Abbreviations: AMB: amphotericin; ANI: anidulafungin; CAS: caspofungin; FLU: fluconazole; ITR: itraconazole; MFG: micafungin; POS: posaconazole; VOR: voriconazole; 5FC: flucytosine.

^a Infection requires debridement in almost all circumstances.

voriconazole, predetermined non-inferiority criteria were not reached.⁸ Additionally, a recent meta-analysis suggested L-AMB may be associated with lower mortality than AmBd during the empiric treatment of neutropenic fever.⁹ AMB was previously the preferred first-line agent during the treatment of invasive aspergillosis; however, a greater therapeutic response and survival have been demonstrated when voriconazole is administered in this setting—relegating AMB to second-line or salvage therapy during the treatment of invasive aspergillosis.¹⁰

AMB does remain the agent of choice when the Zygomycetes are encountered. In fact, a delay in the prescribing of an AMB formulation in patients infected with one of the Zygomycetes resulted in a twofold greater risk for death.¹¹ Discriminating between invasive zygomycosis and aspergillosis is difficult, but the differences in the choice of antifungal agents and outcomes mandate an aggressive diagnostic strategy and prompt initiation of antifungal agents.

Before the development of alternative agents, AMB was the recommended first-line agent for invasive candidial infections.¹² AMB in combination with flucytosine remains the drug of choice in the treatment of cryptococcal meningitis and in most cases a lipid formulation is preferred because of the decreased incidence of nephrotoxicity.⁵ Severe infection caused by the endemic mycoses (i.e. histoplasmosis, coccidioidomycosis, blastomycosis, and sporotrichosis) should be treated with an AMB formulation histoplasmosis remains the only infection for which a lipid formulation of AMB (L-AMB) has demonstrated greater efficacy than the conventional form.¹³

In attempts to avoid the potential nephrotoxicity of systemic administration and to deliver higher local concentrations, different formulations of AMB have been given by way of the inhalational route. The deoxycholate used to solubilize AMB acts as a detergent and may affect alveolar surfactant. Lipid preparations are thus preferred for inhalation delivery, although no decline in pulmonary

lung function from AmBd has been documented. AmBd is often difficult to effectively administer in an aerosol form because of foaming caused by the solubilizing agent.^{11,14-16} Aerosol delivery has been found effective in the prevention of pulmonary fungal infections in lung transplantation and in bone marrow transplant recipients, although data supporting its efficacy in other settings are limited.

Inhaled L-AMB has been found protective against development of invasive aspergillosis when given twice weekly to neutropenic patients who have cancer.¹⁶ Inhalation delivery is also an attractive option in the treatment of lung transplant patients and a recent retrospective series reported nebulized ABLC provided effective prophylaxis against invasive aspergillosis in 98.3 percent of all patients.¹⁴

The recommended dose of IV AmBd is between 0.7 and 1 mg/kg and only recently have clinical data emerged evaluating higher doses of lipid formulations of AMB to potentially improve efficacy. The AmBi Load trial evaluated the efficacy of higher initial doses of L-AmB (3 mg/kg versus 10 mg/kg) in the treatment of invasive aspergillosis. Treatment success rates were similar in both treatment arms although there was a greater incidence of nephrotoxicity in those receiving the higher dose of L-AmB.¹⁷

AmBd infusion is associated with infusion related reactions, such as fever, chills, rigors, myalgias, bronchospasm, nausea and vomiting, tachycardia, tachypnea, and hypertension.¹² These events are less likely to occur when one of the lipid formulations is used; however, ABCD has been associated with the development of dyspnea and hypoxia and L-AMB has been associated with back pain during infusion.⁶ Amphotericin B has been associated with acute kidney injury and nephrotoxicity in many studies and is a well known potential complication of therapy occurring in up to 30 percent of patients. This toxicity is believed secondary to vascular smooth muscle dysfunction with resultant vasoconstriction and ischemia.¹⁸ For this reason most advocate ensuring adequate volume status before administration. Lipid preparations of AMB have a lower incidence of renal toxicity, and studies have shown that when AmBd is replaced by a lipid formulation after the development of creatinine elevation, renal function stabilizes or improves in a significant proportion of patients.¹⁹ The avoidance of AmBd and use of a lipid formulation has been met with skepticism by some because of the vast price difference in compounds. The reduction in hospital days when toxicity is avoided, however, has proven the lipid formulations more cost effective than AmBd.¹⁹

TRIAZOLES

The triazoles also exert their effects within the fungal cell membrane. The inhibition of cytochrome P450 (CYP)-dependent 14- α -demethylase prevents the conversion of lanosterol to ergosterol. This mechanism results in the

accumulation of toxic methylsterols and resultant inhibition of fungal cell growth and replication (Fig. 1). This class of agents has demonstrated species- and strain-dependent fungistatic or fungicidal activity in vitro and the area under the curve (AUC) to MIC ratio is the primary predictor of drug efficacy. The indirect immunomodulatory effects are poorly understood because of the complex interaction of triazoles and phagocytic cells. Evidence suggests that ergosterol depletion increases fungal cell vulnerability to phagocytic oxidative damage²⁰ and voriconazole has been shown to induce the expression of TLR2, nuclear factor- κ B, and tumor necrosis factor- α .² Azoles differ in their affinity for the 14- α -demethylase enzyme and this difference is largely responsible for their varying antifungal potency and spectrum of activity. Cross-inhibition of several human CYP-dependent enzymes (3A4, 2C9, and 2C19) is responsible for most of the clinical side effects and drug interaction profiles that have been described with this class. Itraconazole and posaconazole act primarily as inhibitors of 3A4 and 2C9 with little effect on 2C19. Voriconazole acts as both an inhibitor and a substrate on all three isoenzymes providing ample opportunity for drug-drug interactions because of this frequently shared metabolic pathway. Comprehensive lists of triazole drug interactions can be found elsewhere. Briefly, caution should be used when these agents are concurrently administered with: most HMG-CoA reductase inhibitors, benzodiazepines, phenytoin, carbamazepine, cyclosporine, tacrolimus, sirolimus, methylprednisolone, buspirone, alfentanil, the dihydropyridine calcium channel blockers verapamil and diltiazem, the sulfonylureas, rifampin, rifabutin, vincristine, busulphan, docetaxel, trimetrexate, and the protease inhibitors ritonavir, indinavir, and saquinavir.²¹⁻²⁷

The triazoles have also been associated with QTc prolongation²⁸ and co-administration with other agents known to have similar effects (cisapride, terfenadine, astemizole, mizolastine, dofetilide, quinidine, and pimozide, amongst others) should be avoided.²⁹⁻³¹ The triazoles are additionally embryotoxic and teratogenic and are secreted into breast milk, and thus administration should be avoided during pregnancy or while lactating.^{28,32,33}

FLUCONAZOLE

Fluconazole remains one of the most frequently prescribed triazoles because of its excellent bioavailability, tolerability, and side effect profile. More than 80 percent of ingested drug is found in the circulation, and 60 percent to 70 percent is excreted unchanged in the urine. Oral absorption remains unchanged in patients receiving acid suppressive therapy (proton pump inhibitors, H₂-blockers). Only 10 percent of fluconazole is protein bound.³⁴ Fluconazole also exhibits excellent tissue penetration. CSF levels are 70 percent of matched serum levels, and levels reported in saliva, sputum, and other sites are well

within therapeutic ranges. The half-life is 27 to 34 hours in the presence of normal renal function allowing once-daily dosing. In patients who have a reduced creatinine clearance the normal dose should be reduced by 50 percent. Fluconazole serum levels are rarely necessary. Currently 50-, 100-, 150-, and 200-mg tablets are available and IV formulations exist in 200- or 400-mg doses.

Fluconazole is active against most *Candida* spp. with the exception of *C. krusei* and *C. glabrata* isolates. If a *C. glabrata* isolate is found susceptible to fluconazole higher doses (12 mg/kg/d) should be used.^{7,35} There is no appreciable activity against *Aspergillus*, *Fusarium*, *Pseudoallescheria*, or the *Zygomycetes*.

Although fluconazole has substantially fewer drug-drug interactions than other triazole compounds, caution remains necessary because of increases in the serum levels of phenytoin, glipizide, glyburide, warfarin, rifabutin, and cyclosporine.

Fluconazole levels are reduced in the presence of rifampin. Fluconazole is well tolerated by most patients, even if chronic therapy is necessary.³⁶ Headache, alopecia, and anorexia are the side effects most common (10%) with transaminase elevation in less than 10 percent.

Fluconazole remains the drug of choice in the treatment of oropharyngeal candidiasis (OPC) (6 mg/kg/d for 7-14 days).⁷ Newer data suggest a one-time dosing for the treatment of OPC with equivalent relapse rates to standard therapy.³⁷ Patients who have frequent relapse should remain on chronic suppressive fluconazole until immune reconstitution has been documented. Fluconazole has also been used for prophylaxis in those at high-risk for invasive fungal infections.

Initiation of 6 mg/kg/d of fluconazole for the first 75 days after bone marrow transplantation has been found effective in reducing cases of candidemia.³⁸ Preemptive therapy within ICUs remains controversial. The high incidence of invasive candidiasis within this setting (1-2% of all patients) makes prophylaxis an attractive option; however, the largest randomized, multicenter, blinded clinical trial comparing empiric fluconazole therapy in ICU patients with several risk factors for invasive candidiasis to placebo showed no clear benefit to fluconazole therapy.³⁹

Although recent data has accrued regarding the use of high-dose fluconazole monotherapy during the induction course of cryptococcal meningitis, this practice should be used only in resource limited settings and not when AMB is available.⁴⁰

Fluconazole is also useful for infections caused by *Coccidioides immitis*. In cases of meningitis or disseminated infection high-dose fluconazole is often necessary.⁴¹

ITRACONAZOLE

Itraconazole is currently available as capsules and as an oral solution suspended in hydroxypropyl cyclodextrin

(HPCD). Unfortunately, the IV preparation of itraconazole is no longer commercially available. Itraconazole capsules depend on an acidic environment for maximal absorption, and the concomitant administration of H_2 -receptor antagonists, proton pump inhibitors, or antacids causes erratic and unpredictable drug absorption; it is thus recommended that itraconazole capsules be taken with food or a cola beverage.^{42,43} Itraconazole solution allows for greater oral bioavailability and the AUC and peak concentrations are both increased by 30 percent when itraconazole solution is taken in the fasting state.^{44,45} The cyclodextrin carrier has minimal absorption and no systemic side effects have been attributed to its use in the oral formulation.⁴⁶

With once-daily dosing, steady state is reached in 7 to 14 days, although oral loading allows for more rapid attainment of therapeutic serum levels.⁴⁷ Itraconazole is also highly protein bound with less than 1 percent available as free drug and has a relatively high volume of distribution.

Itraconazole is extensively metabolized by the liver and its major metabolite, hydroxy-itraconazole, does possess antifungal activity similar to that of the parent drug. Despite similar antifungal efficacy, hydroxyl-itraconazole is not measured during serum drug level determination by high performance liquid chromatography, although the active metabolite is detected by bioassay.⁴⁸

The development of newer and more effective antifungal agents (i.e. voriconazole) has relegated itraconazole to second-line therapy during the treatment of invasive aspergillosis. Itraconazole does, however, remain the drug of choice for those who have mild to moderate infection caused by histoplasmosis and is the mainstay of secondary prophylaxis in patients who have HIV with a history of histoplasmosis before immune reconstitution with antiretrovirals.⁴⁹ Itraconazole is also approved for allergic bronchopulmonary aspergillosis.¹⁰

The recommended dosage of oral itraconazole in adults is 400 mg/d (capsules) and 2.5 mg/kg twice daily (HPCD solution).¹⁰ Steady-state levels can be more rapidly attained, however, when administered as 200 mg three times daily for 3 days and then 200 mg twice daily for the duration of therapy. Considerable concern remains regarding adequate oral absorption and oral itraconazole is not recommended in seriously ill patients or patients who have life-threatening disease. Dose adjustment is not indicated when the oral formulation of itraconazole is used in patients who have renal insufficiency or those receiving hemodialysis/continuous ambulatory peritoneal dialysis. The half-life of itraconazole is prolonged in patients who have hepatic dysfunction and drug dose adjustment, liver function testing, and drug interactions need to be carefully assessed.⁵⁰ Itraconazole is usually well tolerated and although adverse reactions have been observed in up to 39 percent of patients no fatalities and only rare toxicity

requiring discontinuation of therapy were reported. The most frequent side effects include: nausea and vomiting (<10%), hypertriglyceridemia (9%), hypokalemia (6%), liver enzyme elevations (5%), skin rashes/pruritus (2%), headache and dizziness (<2%), and pedal edema (1%).⁵¹ Gastrointestinal intolerance (46%) is exceedingly common with the oral HPCD solution at doses greater than 400 mg/d with vomiting the most frequent complaint.⁵²

The myocardial depressant effects of itraconazole are also well known and cases of congestive heart failure have been reported.⁵³

POSACONAZOLE

Posaconazole is a lipophilic second-generation antifungal triazole with a similar molecular structure to that of itraconazole. The spectrum of activity of posaconazole includes agents of the *Zygomycetes*, and it has improved activity against *Aspergillus* spp compared with itraconazole.⁵⁴

Posaconazole is insoluble in water and no IV formulation has yet been developed. It is thus administered as a cherry-flavored suspension using polysorbate 80 as the emulsifying agent.⁵⁵ Optimal dosing of posaconazole is obtained when given as two to four divided doses administered with food or a liquid nutritional supplement.^{56,57} Although initial studies suggested that changes in gastric acidity do not affect posaconazole absorption subsequent work has shown H₂-receptor antagonists and proton pump inhibitors may decrease posaconazole serum levels and if possible coadministration should be avoided.^{32,55,58,59}

Posaconazole has demonstrated dose-dependent pharmacokinetics with saturable absorption greater than 800 mg/d; thus oral loading is not possible and steady state is typically achieved after 7 to 10 days of therapy.⁶⁰ This prolonged time required to reach steady-state levels may affect the use of posaconazole as primary therapy for invasive fungal infections. This agent also has a large volume of distribution despite its high protein binding and a half-life of approximately 24 hours. Peak serum concentrations have shown considerable interpatient variability for reasons that remain unclear. Some have proposed genetic polymorphisms within P-glycoprotein to play a role because posaconazole is both a substrate and inhibitor, but this remains unproven.⁶¹ Glucuronidation plays a minor role in posaconazole metabolism and single nucleotide polymorphisms within UGT (uridine diphosphate glucuronyl transferase) have also been proposed to account for these differences but confirmatory studies are lacking.⁶² This unpredictable variation in serum posaconazole levels has heightened interest and the necessity of therapeutic drug monitoring (TDM).

Posaconazole is hepatically metabolized and undergoes minimal glucuronidation. Renal clearance plays a minor role in the clearance of posaconazole, which is

predominantly eliminated fecally. Oral posaconazole has proved effective in the prevention of proven or probable invasive aspergillosis in neutropenic patients who have acute myelogenous leukemia and in hematopoietic stem cell transplant recipients who have graft versus host disease.^{63,64} The efficacy and safety of posaconazole in the treatment of invasive fungal infections has also been assessed, and although this study predates the development of echinocandins and voriconazole the statistically significant success rate of posaconazole compared with other agents allows for its use during salvage therapy.⁶⁵ Currently, 200 mg three times daily is recommended for prophylaxis, and 800 mg divided in two or four doses is recommended in the salvage setting. For patients not tolerating food, a liquid nutritional supplement has been recommended to increase absorption.⁶¹ Pediatric dosing schedules have yet to be established.¹⁰ Dose adjustment by age, sex, race, and hepatic or renal insufficiency is not necessary given the minimal glucuronidation and renal clearance of posaconazole.⁶⁶

Posaconazole is usually well tolerated and infrequently requires discontinuation because of adverse events. The most frequent side effects of posaconazole therapy are gastrointestinal (14%), with transaminase elevation and hyperbilirubinemia occurring in 3 percent.⁶⁴ In one trial, however, more serious adverse events were reported in patients treated with posaconazole than with fluconazole. Three cardiac events were reported among those possibly related to posaconazole treatment, including decreased ejection fraction, QTc prolongation, and torsades de pointes.⁶³ For most patients posaconazole is well tolerated and even long-term therapy (>6 months) is frequently without toxicity.⁶⁷ Posaconazole is not significantly metabolized through the cytochrome P450 system and serum levels are unlikely to be increased by concomitant administration of P450 inhibitors.

VORICONAZOLE

Voriconazole is a low molecular weight water soluble second-generation triazole with a chemical structure similar to fluconazole. Voriconazole exhibits a broad spectrum of activity against molds with the exception of the *Zygomycetes*.⁶⁸ Voriconazole is available in oral and IV formulations. Similar to itraconazole, the IV form depends on sulfobutyl ether β -cyclodextrin for solubility.⁶⁸ When 3 to 6 mg/kg of daily voriconazole is administered, steady-state levels are reached in 5 to 6 days. If IV loading is given, however, steady state can be reached within 1 day.⁶⁹ The oral formulation obtains steady-state levels within 24 hours if appropriate loading is administered; however, fatty foods have been found to reduce bioavailability by 80 percent.⁷⁰ Although voriconazole in children has demonstrated linear pharmacokinetics, in adults nonlinear metabolism is observed, likely secondary

to saturable metabolic enzymes required for drug clearance.⁶⁹ Interpatient serum concentration differences have been attributed to polymorphisms within CYP2C19, the major metabolic pathway for voriconazole.⁶⁸ Up to 20 percent of non-Indian Asians have low CYP2C19 activity and voriconazole serum levels are thus up to four times higher than those found in white or black populations in which the “poor metabolizer” status is uncommon.⁷¹ The unpredictability of patient enzymatic activity has generated an increased interest in the routine use of voriconazole serum level determination. For IV administration 6 mg/kg twice daily on day one, followed by 4 mg/kg IV twice daily for the duration of therapy is recommended. The oral dosages in adults are also weight based. For those weighing greater than 40 kg, 400 mg twice daily on day one, followed by 200 mg twice daily until completion of therapy is suggested, whereas those weighing less than 40 kg should receive 200 mg twice daily for one day followed by 100 mg twice daily.⁶⁸ Pediatric patients are known to hypermetabolize voriconazole and for this reason an IV dose of 7 mg/kg twice daily and oral dosing of 200 mg twice daily without loading is recommended.³³ In patients who have liver dysfunction standard loading doses should be given, but the maintenance dose is reduced by 50 percent. The safety of voriconazole use in severe liver disease remains uncertain. No dosage adjustment is required if oral drug is given to patients who have renal insufficiency.

The presence of a cyclodextrin vehicle within the IV formulation has caused concerns about vehicle accumulation in renal insufficiency or dialysis dependence and IV administration is best avoided in patients who have a creatinine clearance less than 50 mL.⁶⁸

Voriconazole is typically well tolerated, and the side-effect profile is similar to other triazoles with few exceptions. Most of those experiencing a reported adverse reaction to voriconazole describe abnormal vision (up to 23%) that is transient, infusion related, and without sequelae. This unique effect typically occurs 30 minutes after infusion and abates 30 minutes after onset. Other well-known effects of voriconazole therapy include skin rash and transaminase elevation.⁷² Baseline evaluation of hepatic function has been recommended before and during treatment, and rare cases of hepatic failure during voriconazole use have been reported.⁷³ Elevated voriconazole serum levels have been attributed to most side effects encountered in clinical practice, and higher levels (>5.5 mg/L), although associated with favorable outcomes, have also been suggested to be responsible for the uncommon potential side effects of encephalopathy or hallucinations.⁷⁴⁻⁷⁶

Voriconazole has become the drug of choice for most cases of invasive aspergillosis based on recent data comparing voriconazole to conventional amphotericin B, followed by other antifungal therapy in patients who have invasive aspergillosis.⁷⁷ Voriconazole has also been

evaluated in the treatment of neutropenic fever. Although, voriconazole did not meet predetermined non inferiority criteria, there were significantly fewer breakthrough infections (including those caused by *Aspergillus* spp.) in patients receiving voriconazole.⁸

Voriconazole has also been evaluated for use during infection caused by *Fusarium* and *Scedosporium* spp. A retrospective series evaluated its use in these infections and reported a favorable response in 63 percent of patients treated with voriconazole.³³

ECHINOCANDINS

Echinocandins (caspofungin, micafungin, anidulafungin) are synthetic compounds that inhibit the synthesis of β -1,3 glucan, by inhibiting the activity of glucan synthase. This mechanism impairs cell wall integrity and leads to osmotic lysis.⁷⁸ Their clinical use is primarily limited to *Candida* spp. and *Aspergillus* spp. and they lack activity against the *Zygomycetes*, *Cryptococcus* spp, and other clinically important molds (Table 1). Although activity is observed against all *Candida* spp, the MICs are elevated (>1 mg/mL) when *Candida parapsilosis* and *Candida guilliermondii* are encountered and susceptibility differences between the different agents in this class are minimal.⁷⁹ Echinocandins also have immunomodulatory effects. By exposing β -glucan by the disruption of fungal cell wall mannoproteins, additional antigens are exposed for antibody deposition and fungal recognition by the host immune system.⁸⁰ Echinocandin efficacy is predicted by peak to MIC ratios, and optimal fungicidal activity is obtained when peak concentrations exceed MICs by 5 to 10-fold.⁶ TDM of echinocandins is seldom required, however, and not routinely recommended. Echinocandin resistance is uncommon but may develop during therapy.⁸²

Multiple *in vitro* studies have confirmed a paradoxical effect of the echinocandins. In this circumstance, above a certain concentration of drug decreased antifungal activity is observed. The exact mechanism responsible for this phenomenon has not been fully elucidated and the clinical significance remains uncertain.⁸⁵

Echinocandins have poor oral absorption and current agents are available only in the IV formulation. Echinocandins are highly protein bound (anidulafungin 84 percent, caspofungin 97 percent, and micafungin 99%) and have a half-life of 26, 30, and 15 hours, respectively. Their vitreal and CSF penetration is negligible and this point is of clinical significance during the treatment of candidemia if endophthalmitis is also observed.

Caspofungin was the first available agent of this class, and is metabolized by both hepatic hydrolysis and N-acetylation. Inactive metabolites are subsequently eliminated in the urine. Severe hepatic dysfunction thus mandates caspofungin dose reduction.⁶ Caspofungin has several

drug interactions with agents metabolized through the cytochrome P450 system and serum levels are reduced in the presence of rifampin and may increase levels of sirolimus, nifedipine, and cyclosporine.⁶ Micafungin is metabolized by nonoxidative metabolism within the liver and anidulafungin undergoes nonenzymatic degradation within the kidney. Both agents are eliminated in stool. These agents therefore do not require dosage adjustment with hepatic impairment.⁶

The side effect profile of the echinocandins is minimal and these agents are typically well tolerated. An infusion-related reaction has been described if rapid administration is given, with tachycardia, hypotension, or thrombophlebitis.

The increased incidence of triazole-resistant *Candida* spp and the fungicidal activity of the echinocandins (caspofungin, micafungin, anidulafungin) has prompted some authorities to recommend these agents as first-line therapy for invasive candidiasis. Additionally, their proven efficacy, infrequency of side effects, and favorable drug interaction profiles make them attractive options over other available antifungals.^{12,83–85} Comparative trials have found the echinocandins equally efficacious and better tolerated than AMB in the treatment of candidemia.¹² In one such trial, caspofungin (70 mg loading dose followed by 50 mg daily) was compared to amphotericin B deoxycholate (0.6–1 mg/kg) in the treatment of invasive candidiasis. Although *C. albicans* was more common in the AMB arm, modified intention to treat revealed similar survival in each group, with a trend toward increased survival and a statistically significant decrease in drug side effects in those receiving caspofungin.¹²

Similarly, micafungin (100 mg IV daily) has been compared to L-AMB 3 mg/kg IV daily in an international, double-blind trial. In this study assigning patients to 14 days of IV treatment, successful treatment was equivalent in each group. There were fewer treatment-related adverse events, including those that were serious or led to treatment discontinuation, with micafungin than there were with liposomal amphotericin.⁸³

It is common practice from the results of these trials for local resistance patterns and the severity of infection to be taken into account and echinocandins are frequently used as first-line therapy.

After clinical improvement is obtained or the absence of fluconazole resistance documented, therapy is often changed to a triazole, such as fluconazole. As noted previously, CNS and intraocular infections should not be treated with echinocandin monotherapy because of their poor penetration into these sites.

Although clinical trials have been primarily limited to patients who have candidemia, observational data have shown efficacy in candidal osteomyelitis, peritoneal infections, and abdominal abscesses.⁸⁶ Additional retrospective

data have also shown a potential role for the echinocandins in infective endocarditis caused by *Candida* spp.⁸⁷

The echinocandins have also been found efficacious in the treatment of invasive aspergillosis, although they are fungistatic against this agent. The growing number of patients who are at risk for this infection has prompted a greater interest in the use of other agents that may be of clinical use against this devastating infection. The known toxicity of AMB and its different formulations and the potential for voriconazole-induced drug-drug interactions or toxicity has also increased interest in the echinocandins for use during treatment of IA.⁸⁸

Caspofungin as a potential first-line agent has been evaluated only in limited settings and although acceptable responses have been observed, data are not sufficient to recommend caspofungin for first-line use during the treatment of IA.¹⁰ Patients who are unresponsive or intolerant to voriconazole may benefit from a change to caspofungin.⁸⁸ *In vitro* studies and limited clinical data have also shown the potential role for combination therapy (an echinocandin plus AMB or an azole) and prospective studies are ongoing.

ANTIMETABOLITES

Flucytosine

Flucytosine (5FC) is deaminated to 5-fluorouracil by fungal cytosine deaminase. 5-fluorouracil is further converted to 5-fluorodeoxyuridylic acid, which interferes with DNA synthesis.

Mammalian cells lack cytosine deaminase allowing for a selective inhibition of fungal organisms.⁹⁹ This agent may be either fungistatic or fungicidal depending on fungal species and strain. Activity has been observed against most fungal pathogens, including *Candida*, *Cryptococcus*, *Cladosporium*, *Phialophora*, and *Saccharomyces* spp. *Aspergillus* spp, the *Zygomycetes*, dermatophytes, and the endemic mycoses are all resistant to 5FC.

Additionally, resistance commonly develops when 5FC is used as monotherapy even in susceptible organisms and it should not be used as such except during the treatment of chromoblastomycoses or during the treatment of localized candidal infections when alternative agents are unavailable or contraindicated. 5FC has excellent oral bioavailability with greater than 80 to 90 percent absorption. Peak serum levels occur 1 to 2 hours after ingestion (30–45 mg/ml) of a single dose. The volume of distribution of 5FC is 0.6 to 0.9, yet bone, peritoneal, and synovial fluid 5FC levels have been demonstrated and urinary levels are several-fold higher than concurrent serum levels. Greater than 95 percent of 5FC is eliminated unchanged in the urine. 5FC is typically administered by mouth at 100 or 150 mg/kg/d divided in four doses.

Side effects of therapy include rash, diarrhea, hepatic transaminase elevation, and bone marrow suppression. The marrow suppressive effects are more common if blood levels exceed 100 to 125 mg/mL.⁹⁰ In the presence of prolonged therapy (>7 days) or with alterations in renal function serum drug monitoring is recommended. Other less common side effects, such as abdominal pain or diarrhea, are frequently indirect markers of elevated flucytosine levels and therapy is typically stopped in these circumstances. 5FC is teratogenic and should not be administered during pregnancy.

5FC is primarily used only in the treatment of *Cryptococcus* (combined with AMB) and chromoblastomycosis. Despite concerns for additive toxicity the synergistic effects of dual therapy in *Cryptococcus* allow for more rapid CSF clearance.⁹¹

SUMMARY

The incidence of infection with invasive mycoses continues to increase with the increasing immunosuppressed patient population. The recently expanded antifungal armamentarium offers the potential for more effective and less toxic therapy and these agents offer distinct pharmacologic profiles and indications for use.

Approach to the Child with Fever of Unknown Origin

Vijay Yewale, Dhanya Dharmapalan

INTRODUCTION

Fever of unknown origin (FUO) is best defined as fever without obvious source on initial clinical examination and then classified into acute (illness of ≤ 1 week's duration) and prolonged (>7 to 10 days' duration).¹

Most of the fevers of unknown origin result from atypical presentations of common diseases whose definitive diagnosis can be established only after prolonged observation. This is especially true in connective tissue disorders where one has to let time uncover the true facet of the disease as initial clinical examination and laboratory results can be normal.

ETIOLOGY

The most common etiology of fever of unknown origin (FUO), both acute and prolonged is infection.²

Infections contribute to 40 to 50 percent cases of FUO followed by collagen vascular disease (15-20%) and malignancy (5-10%). In about 10 to 20 percent cases, a definite diagnosis is never established.

It is useful to recognize that uncommon manifestations of common diseases are more likely than are rare diseases.

Approach to a Child with FUO

All toxic-appearing infants and children and all febrile infants less than 28 days of age should be hospitalized for evaluation and initiation of prompt parenteral antibiotic therapy after sending blood culture. Toxic appearance is a clinical presentation characterized by lethargy, poor perfusion, marked hypo/hyperventilation and cyanosis.

Febrile infants and young children have, by tradition, been arbitrarily assigned to different management strategies by age group: neonates (birth to 28 days), young

infants (29 to 90 days), and older infants and young children (3 to 36 months).³

In all neonates, a complete septic screening which includes CSF with prompt initiation of antibiotic therapy should be done.

The two most important steps in evaluating any child with FUO is a good history and a thorough physical examination.

History

The importance of a good history in evaluating a FUO cannot be overstressed. The history should elicit the details of onset of fever, intensity, pattern, if associated with chills/rigors and other associated symptoms. Many a times, the caretaker may give a history of ten days fever but only after digging properly into the history, the physician may realise that the child had fever for two days a week back and has again got fever since a day after a brief normal afebrile interval. This pattern associated with back to back inter-current viral illnesses is not uncommon in practice.

Many a times, in cases of undocumented fever, the child may be afebrile but the caretaker may wrongly perceive fever due to warm head and palms as compared to the rest of the body.

In neonates and small infants, there may be increased temperature due to overbundling and on recording temperature after removing excess clothes, the child may be found to be afebrile.

Immunization history is important especially in view of era of vaccines available against Hib, *Pneumococcus*, enteric fever, hepatitis A, B, influenza.

Travel history, exposure to pets, consumption of unpasteurised dairy products, family history, contact history with active tuberculosis and drug history need to be asked.

Physical examination

The first aim of a physical examination is to judge whether the illness is acute or chronic and the severity of the illness for any needed prompt action. Vitals should be recorded and a thorough general and systemic examination should be done. Lymphadenopathy, hepatosplenomegaly or rash may not help to pinpoint the system involved but at least will indicate some systemic illness. However, a repeated daily physical examination looking for new signs like rashes, murmur, joint involvement, etc is the best strategy as many of the conditions that cause FUO may have an absolutely normal physical examination to begin with.

Investigations

It is not wise to run a long battery of tests blindly in a FUO. The investigations should be guided by the most probable differentials resulting out of proper history and examination. The decision of the investigations to be carried out is also influenced by the host factors like age and local endemic diseases like malaria, chikungunya, etc.

It is also important that the most common etiology should be ruled out first before proceeding for tests for a lesser probable cause.

The initial investigations should include a complete blood count with a good look at the peripheral smear, a routine urine examination, blood culture, an X-ray chest and a CSF examination in any signs of neurological involvement. A Mantoux test may be useful additional tool to rule out tuberculosis. Similarly, a normal ESR count though nonspecific, is unlikely to be present in rheumatological or malignant conditions. Sometimes multiple blood cultures may be required to establish a diagnosis of subacute endocarditis or osteomyelitis.

CBC is not a sensitive and specific test to differentiate between viral or bacterial infections and may be even normal at the onset of a chronic illness. However, a total leukocyte count of $<5000/\text{mm}^3$ may rule against a serious bacterial infection except in typhoid fever or in neonates. Similarly, a total leukocyte count greater than $15000/\text{mm}^3$ with increase in nonsegmented polymorphonuclear leukocytes $> 500/\text{mm}^3$ indicates a serious bacterial infection. Though a lot of progress has been made in diagnostic tools to detect serious bacterial infections in young like CRP, procalcitonin, interleukin-6, unfortunately there is still no single marker available to diagnose a serious bacterial infection.

It is necessary to look at serial CBCs to detect rise or fall in platelet count or other changes in the differential counts. It is known that parasites like malaria may not be picked up in a single smear examination.

Further investigations like imaging/ 2D echocardiography/serology tests may be carried out depending on the

emergence of new signs or symptoms and on the basis of the results of primary investigations.

Major difficulties in the management of FUO in children in developing countries include constraints in the availability and reliability of laboratory tests, cost, misuse of antibiotics and difficulties encountered in the diagnosis of malaria and typhoid fever.⁴ Of these, irrational antibiotics in terms of the choice, duration and compliance results in the menace of both partially treated infections and atypical course of the infection with the worst scenarios of producing multi drug resistance. To add to the woes is immune mediated fevers triggered by many illnesses ranging from a simple viral fever to malaria or enteric fever, where fever continues even after the underlying infectious process is controlled.

Infections

Among infections, since viral illnesses are usually self limiting, bacterial infections are more common agents resulting in a FUO. *The bacterial infections may be localized for example: abscess, chronic mastoiditis, sinusitis, osteomyelitis, septic arthritis, pyelonephritis, endocarditis or generalized like tuberculosis, salmonellosis, brucellosis.*

Many times prolonged presentations of common viral diseases may also present as a FUO. *Other viral illnesses can cause FUO are cytomegaloviral infections, Hepatitis virus, Infectious mononucleosis and HIV.*

Other common infective causes are parasitic (malarial, amoebiasis, toxoplasmosis), rickettsial, chlamydial and fungal infections.

In a hospital based, prospective, observational study on children between 3 years and 12 years, it was found that a diagnosis was reached in 88 percent cases of FUO. Infections were the predominant cause of FUO in 69 percent. Enteric fever was the most common infection, followed by visceral leishmaniasis and tuberculosis.⁵

One study found that about 34 percent of cases of prolonged FUO caused by infections, bacterial meningitis and urinary tract infection accounting for about 6.5 percent and 11.4 percent, respectively.⁶

The investigations for infectious etiology should be guided by the history of local endemicity, travel history to endemic areas of malaria, etc. consumption of unpasteurised milk (brucellosis), contact history with active tuberculosis (for tuberculosis).

Malignancies

Since most of the childhood cancers are curable, it is very crucial that they are diagnosed at an early stage. Unfortunately, there can be delays in the diagnosis because the signs and symptoms of malignancy may be initially misdiagnosed as infection. A study which tried to evaluate this

initial misdiagnosis of malignancy as infection found that seventy-one percent of the children in the study had fever (most of which were subsequently diagnosed with leukemia).⁷

To look for any signs of malignancy particular attention should be paid during the physical examination to the four Bs—"blood, brain, belly and bone".

*The most common childhood malignancies are acute lymphoblastic leukemia, central nervous system (CNS) tumors and lymphomas.*⁸

Fever may be low grade in leukemia. Leukemia should be suspected if fever is accompanied by evidence of weight loss, abnormal bleeding, bone pain, lymphadenopathy or hepatosplenomegaly.

It has been suggested that paraneoplastic fevers may be more responsive to nonsteroidal anti-inflammatory drugs than are nonneoplastic fevers, and use of the "Naprosyn test" may offer some direction towards the diagnosis of malignancy.

The presenting symptoms of a brain tumor may include elevated intracranial pressure, nerve abnormalities and seizures. In children, lymphoma may present as one or more painless masses, often in the neck, accompanied by signs and symptoms resulting from local compression, as well as signs and symptoms of systemic disturbances, such as fever and weight loss. It is not necessary to see blast cells in peripheral smear and many times leukemia may only have blast cells in their bone marrow.⁸

Bone marrow should be done in clinical suspicion with laboratory findings of anemia, especially if accompanied by reticulocytopenia or a high mean corpuscular volume, thrombocytopenia, leukopenia or leukocytosis. Leukemia may also be considered in a child with high ESR count but a normal platelet count.

Imaging will be diagnostic in detecting solid tumors.

Collagen Vascular Diseases

Five to twenty percent of FUOs in childhood are caused by collagen vascular disease. *The most common rheumatic diseases to present with fever in childhood are systemic onset juvenile arthritis, systemic lupus, and Kawasaki disease.* The diagnosis of rheumatological conditions is usually based on a set of defined criteria rather than a single test.⁹

Systemic Onset Juvenile Arthritis

The fever in systemic onset juvenile arthritis is characteristically quotidian with high once or twice daily spiking fever, $>39^{\circ}\text{C}$, which returns to baseline. The fever spikes occur in the afternoon or evening. The child appears normal during the afebrile intervals. Each fever spike is associated with an evanescent linear or circular salmon pink

macular rash on the trunk and proximal extremities which may elicit a koebner phenomenon. Other features like arthritis, hepatosplenomegaly, lymphadenopathy or pericarditis may be present. The complete blood count may reveal anemia, leukocytosis, thrombocytosis and a high ESR but are nonspecific. The rheumatoid factor and anti-nuclear antibody tests are usually negative. The diagnosis is made easier by the American College of Rheumatology Classification for juvenile arthritis.

Systemic Lupus Erythematosus SLE

Systemic lupus erythematosus should be suspected specially in girls above 8 years of age with mild-moderate fever associated with multisystem involvement. The systemic involvement may be in the form of weight loss, arthritis, malar rash, nephritis, pericarditis, pleuritis or seizures. The complete blood count may suggest anemia, leukopenia, lymphopenia, or thrombocytopenia. Urine may show proteinuria, hematuria or cellular casts. A positive ANA is a hallmark, anti-DNA antibodies and other autoantibodies like rheumatoid factor, antiphospholipid antibodies may also be positive.

Kawasaki Disease

It is the most common febrile vasculitis which can present as FUO especially in younger children. Fever is characteristically high (104°C F or higher), remittent and unresponsive to antibiotics. The fever may even persist for 3 to 4 weeks without treatment. In a classic presentation of Kawasaki, there should be persistence of fever for at least 5 days, with either of the following 4 features like bilateral bulbar conjunctival injection without exudates, mucosal changes in lips and oral cavity, polymorphous exanthema, cervical adenopathy and changes in extremities like edema, rash or periungual peeling (in second/third week).

The diagnosis is mainly clinical. Lab findings reveal systemic inflammation but are nonspecific. The acute phase is characterized by a leukocytosis with a neutrophilic predominance, mild anemia and elevated acute phase reactants. Mildly elevated liver enzymes and a sterile pyuria can also be seen. Thrombocytosis typically develops in the second week, sometimes exceeding $10,00,000/\text{mm}^3$. Antinuclear antibody tests and rheumatoid factors are negative. 2D echo is of utmost importance to evaluate the coronary artery abnormalities.

The diagnostic challenge occurs in atypical or incomplete Kawasaki disease where there may be persistent fever but fewer than four features. Recognition depends on the knowledge of the characteristic features and a high index of suspicion.

This condition is treated with IV immunoglobulins and high dose aspirin.

MISCELLANEOUS

Drug Fever

Drug fevers usually have a constant elevation of fever and disappears within 72 hours of discontinuation of the offending drug. The most common are beta-lactam antibiotics, procainamide, isoniazid, alpha-methyldopa, quinidine and diphenylhydantoin. Slowly metabolised drugs like which contain iodides can cause fever up to one month of discontinuing it.

Periodic Fever's Syndrome

These are rare syndromes where the child presents with episodes of high grade fever lasting for several weeks to months followed by fever free periods of variable duration. Several genes have been identified to be responsible for the familial variety of periodic syndromes. These children may respond poorly to antipyretics.

Prognosis of Fever of Unknown Origin

The prognosis of childhood FUO depends on the underlying etiology. However in comparison to mortality rate of 25 to 40 percent in adults, the mortality in children due to FUO is low (10%).²

Conclusion

In spite of the best advancements for diagnosis of the etiology for fever, the golden strategy remains that of the basic art of medicine, i.e. a good history and repeated clinical examination.

INTRODUCTION

Sepsis is a clinical syndrome subsequent to invasion of the blood stream by microbes triggering off a systemic inflammatory response, the severity of which determines the clinical manifestations ranging from early signs of circulatory compromise to shock, multiorgan dysfunction and death. The infection can be caused by bacteria, viruses, fungi, parasites or the toxic products of these microbes. Globally sepsis is a major health problem with a high mortality and appears to be increasing¹⁻³ in view of the sizeable susceptible population especially the immunocompromised, awareness and advances in pediatric intensive care and emerging and drug resistant bacteria. The incidence is inversely related to the age of the child. Early recognition and intervention holds the key to a favourable outcome. The mortality reported varies from 10 to 40 percent being higher in resource poor developing countries.

ETIOLOGY

Infection leading to sepsis can be caused by a myriad of bacteria, viruses, fungi, parasites. The infection per se or the toxic products of these microbes together with the numerous host factors can start the cascade of inflammatory response leading to the clinical syndrome.

Bacteria like *S. pneumoniae*, *H. influenzae B*, *N. meningitidis*, *S. aureus* and *Salmonella* are important in community while gram-negative bacilli like *E. coli*, *Klebsiella*, *Pseudomonas*, *Enterobacter*, *Acinetobacter*, *Serratia* and *Burkholderia* are important nosocomial infections.

Dengue virus is an emerging pathogen in the developing world. *Candida* especially *nonalbicans* is an emerging nosocomial fungal organism.

Malaria is an important parasite leading to sepsis syndrome.

PREDISPOSING FACTORS

- Immunocompromised (primary or secondary affecting the T cells, B cells, complement)
- Hemoglobinopathies esp. Sickle cell
- Genitourinary anomalies
- Congenital cardiac malformations
- Infected trauma and burns
- Splenic dysfunction/splenectomy
- Hematologic or solid organ malignancy and chemotherapy
- Hospitalization in intensive care settings
- Indwelling catheters/prosthetics and devices

PATHOGENESIS

Systemic inflammatory response syndrome (SIRS) triggered by infection is a necessary cause of sepsis spectrum (Fig. 1). SIRS can also be triggered by chemical, trauma, malignancy, autoimmunity and idiopathic insults. The inflammatory cascade that ensues is a complex process that involves humoral and cellular responses, complement, and cytokine cascades. The relationship has been aptly summarized by Bone et al as a three stage process⁴ (Flow chart 1).

Stage I: In response to an insult, local cytokine production recruits the reticuloendothelial system to contain the noxious stimulus.

Stage II: Small quantities of local cytokines are released into circulation which recruits the macrophages and platelets. The proinflammatory mediators and the acute phase response is checked by stimulation of anti-inflammatory mediators like interleukin (IL)-4, 6, 10, PGE2, protein C, Lipoxins, GM-CSF, TGF and IG-1RA to achieve homeostasis.

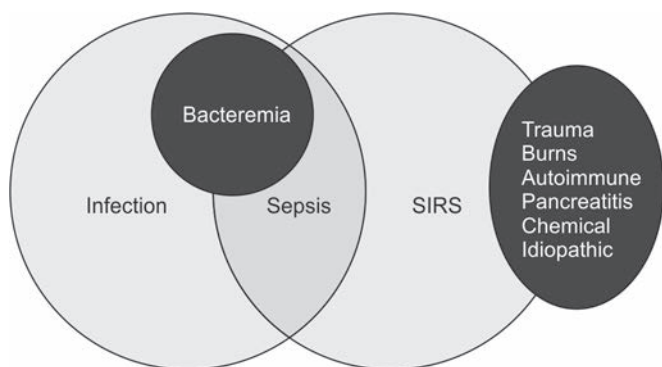

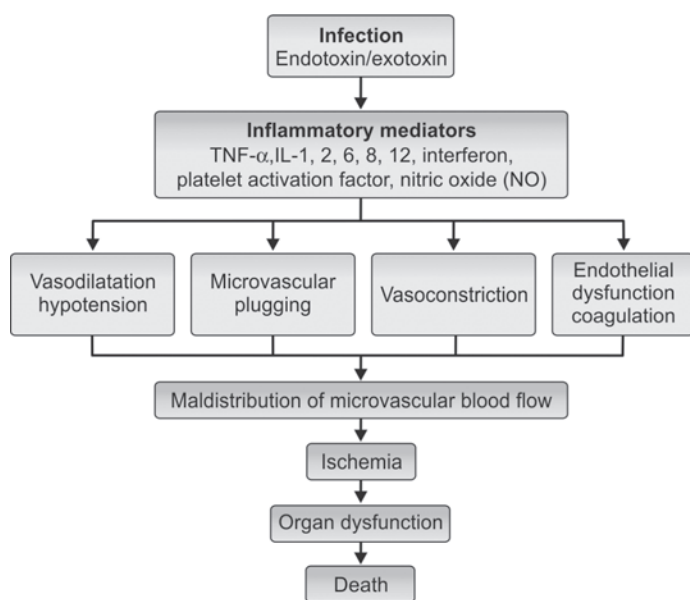

Fig. 1: Infection and SIRS

Flow chart 1: Pathophysiology of systemic inflammatory response syndrome

Stage III: If homeostasis is not restored, a significant systemic reaction occurs. The surge of proinflammatory cytokines TNF- α , IL-1, 6, 8, platelet activating factor, interferon gamma, PGE, leukotrienes and nitric oxide (NO) leads to loss of capillary integrity and maldistribution of microvascular blood flow leading to organ injury and dysfunction.

The inflammatory cascade in infections is often initiated by endotoxin or exotoxin of the invading microbe. TNF- α , IL-1 and the microbial endotoxin or exotoxin lead to cleavage of the nuclear factor- κ B (NF- κ B) inhibitor. Once the inhibitor is removed, NF- κ B is able to initiate the production of mRNA, which induces the production of other proinflammatory cytokines. Both TNF α and IL-1 can be released in large amounts within minutes of an insult and cause fever, hypotension, lung injury and release of stress hormones (norepinephrine, vasopressin, activation of the renin-angiotensin-aldosterone system). IL-6 stimulate the release of acute-phase reactants such

as C-reactive protein (CRP) and procalcitonin. Activation of the coagulation cascade, complement cascade, and the release of nitric oxide, platelet-activating factor, prostaglandins, and leukotrienes is both the cause and effect of cytokine surge. Prostaglandins and leukotrienes incite endothelial damage, leading to multiorgan failure. Polymorphonuclear cells are inhibited to prevent excessive inflammation losing their microbicidal potential.⁵

The procoagulant state mediated via endothelial damage by TNF- α and IL-1 is critical for disease progression. Tissue factor mediated production of thrombin, impaired fibrinolysis due to plasminogen activator inhibitor 1 mediated by TNF α and IL-1, inhibition of anti-inflammatory mediators antithrombin and activated protein-car critical for microvascular thrombosis causing organ dysfunction.

The counter inflammatory response syndrome (CARS) mediated through anti-inflammatory IL-4, IL-10, and antagonists to TNF- α and IL-1 receptor is often overwhelmed by SIRS resulting in an unfavorable outcome. It is believed that because of CARS, agents used to inhibit proinflammatory mediators can deleterious immunosuppression.

DEFINITIONS

The widely followed definitions of pediatric sepsis spectrum have been given by international consensus conference, 2005 and are given in Tables 1 and 2.⁶

CLINICAL PRESENTATION

The importance of a detailed history of the child from a reliable source cannot be undermined. Fever is the most common presenting symptom of children with sepsis syndrome along with fast heartbeats, rapid or labored breathing, cool extremities, or color changes. The child's activity, refusal of feeds, urine output and exposures to infectious illnesses and other sources of insult are important. Verify immunization and drug allergy statuses. A complete physical examination of the infant or child with suspected SIRS is most important. Subtle changes in vital signs (e.g. minimal tachycardia, widened pulse pressure, minimal tachypnea, and minimally delayed capillary refill) may be the first signs of impending SIRS. Hypotension, mental status changes, and anuria are late signs of SIRS. Hypothermia is often a more ominous sign than fever. If SIRS is identified and reversed early, the subsequent inflammatory cascade can often be avoided or mitigated. However, in some situations, further damage occurs because the insult or the resultant host immune response is too great. This damage can result in increased cardiac output, peripheral vasodilatation, increased tissue oxygen consumption, and a hypermetabolic state (warm shock). As the severity increases, cardiac output may fall, peripheral vascular resistance may increase, and shunting of blood may ensue (cold shock). This results in tissue hypoxia, end-organ

Table 1: Definition of sepsis

A. Systemic inflammatory response syndrome (SIRS)	
The presence of at least two of the following four criteria, one of which must be abnormal temperature or leucocytes count:	
<ol style="list-style-type: none"> 1. Core (oral or rectal) temperature of $>38.5^{\circ}\text{C}$ or $<36^{\circ}\text{C}$. 2. Tachycardia, in the absence of external stimulus, chronic drugs, or painful stimuli; or otherwise unexplained persistent elevation over a 0.5 h time period or for children <1 year old: bradycardia, in absence of external vagal stimulus, β-blocker drugs or congenital heart disease or persistent depression over a 0.5 h time period. 3. Tachypnea for an acute process not related to underlying neuromuscular disease. 4. Leukocytes count elevated or depressed for age (not secondary to chemotherapy-induced leukopenia) or $>10\%$ immature neutrophils. 	
B. Infection	
A suspected or proven infection caused by any pathogen or a clinical syndrome associated with a high probability of infection. Evidence of infection includes positive findings on clinical examination, imaging, or laboratory tests (e.g. leukocytes in a normally sterile body fluid, perforated viscus, chest radiograph consistent with pneumonia, petechial or purpuric rash, or purpura fulminans) or a positive culture, tissue stain or polymerase chain reaction test.	
C. Sepsis	
SIRS in the presence of or as a result of suspected or proven infection.	
D. Severe sepsis	
Sepsis plus one of the following: cardiovascular organ dysfunction or acute respiratory distress syndrome or two or more other organ dysfunctions. Organ dysfunctions are described in (Table 2).	
E. Septic shock	
In a child with sepsis presence of; hypotension (systolic BP <70 mm Hg in infant; $<70 + 2 \times \text{age}$ after 1 year of age) or need for vasoactive drug to maintain BP above fifth centile range (dopamine >5 mcg/kg/ min or dobutamine, epinephrine or norepinephrine at any dose) or signs of hypoperfusion—any three of the following: decreased pulse volume (weak or absent dorsalis pedis pulse), capillary refilling time $>3\text{s}$, tachycardia heart rate, core (rectal/oral) to peripheral (skin-toe) temperature gap $>3^{\circ}\text{C}$ and urine output <1 ml/kg/h (<20 ml/h in >20 kg child) or sepsis and cardiovascular organ dysfunction as defined in (Table 2)	
F. Multiple organ dysfunctions	
The detection of altered organ functions in the acutely ill patient constitutes multiple organ dysfunction syndrome (MODS; two or more organs involvement).	

dysfunction, metabolic acidosis, end-organ injury and/or failure, and death.

A meticulous search for localizing signs of infection should be done. A petechial or purpuric rash associated with fever is seen in meningococcal and some hemorrhagic viral infections. Increased effort of breathing with bilateral wheeze or crepitations and unequal breath sounds are pointers toward primary lung pathology or early ARDS. Tense abdomen with a localized guarding or rigidity is due to an abdominal localization of infective focus. Frequent reassessment for and during interventions is the key to success.

The cardinal signs:

- Fever
- Leukocytosis
- Tachypnea
- Tachycardia
- Reduced vascular tone
- Organ dysfunction
- Mental alertness

INVESTIGATIONS

The laboratory evaluation is essential for:

- Etiology and the source of infection
- Evaluation of organ systems
- Monitoring

Cultures of blood, urine, all available body fluids and secretions including skin and cellulitic areas may give a clue to the offending microbe and the source of infection. CSF must be evaluated as and when the clinical condition is stabilized. The positive yield from the culture is invariably around 45 percent.⁷ Viral infections are often not amenable to culture and serology is often relied upon. Newer nonculture based molecular diagnostics like PCR are becoming important.⁸

High or extremely low leukocyte counts with band cells and toxic granules are suggestive of infection. Hemoconcentration helps assess the hydration status. LFT, KFT, electrolytes, amylase, lactate and arterial blood gases help assess and monitor organ dysfunction. Assessment of coagulation is essential in children with SIRS. The role of

Table 2: Organ dysfunction criteria*Cardiovascular dysfunction*

- Hypotension (systolic BP <70 mm Hg in infant; < 70 + 2 × age after 1 year of age) or
- Need for vasoactive drug to maintain BP above the fifth centile range (dopamine >5 mcg/ kg/ min or dobutamine, epinephrine or norepinephrine at any dose) or
- Signs of hypoperfusion—any three of the following; decreased pulse volume (weak or absent dorsalis pedis pulse), capillary refilling time >3s, tachycardia heart rate, core (rectal/oral) to peripheral (skin-toe) temperature gap >3°C and urine output <1 ml/ kg/ h (<20 ml/h in >20 kg child)
- In early stage, there is an increase in heart rate and poor peripheral perfusion in form of weak pulse and prolonged capillary refill time. Hypotension occurs late, and may lead to precipitous cardiac arrest.

Respiratory dysfunction

- Proven need for supplemental oxygen or >50% FiO₂ to maintain saturation >92% or
- Need for nonelective mechanical ventilation or
- PaO₂/FiO₂ <300 in absence of cyanotic heart disease or pre-existing lung disease or
- PaCO₂ >65 torr or 20 mm Hg over baseline PaCO₂

Neurologic dysfunction

- Glasgow coma scale <11 or
- Acute change in mental status with a decrease in Glasgow coma score >3 points from abnormal baseline

Hematological dysfunction

- Platelet count <80,000/ mm or a decline of 50% in platelet count from highest value recorded over the past 3 days [for chronic hematology/oncology patients] or
- International normalized ratio >2

Renal dysfunction

- Serum creatinine > 1 mg/ dL

Hepatic dysfunction

- Total bilirubin >4 mg/dl (not applicable for newborn) or alanine transaminase 2 × upper limit of normal for age

Acute respiratory distress must include a PaO₂/FiO₂ ratio <200 mm Hg, bilateral infiltrates, acute onset and no evidence of left heart failure. Acute lung injury is defined identically except the PaO₂/FiO₂ ratio must be <300 mm Hg.

acute phase reactants like ESR, CRP, procalcitonin interleukins and TNF- α is debatable.

Imaging studies like chest X-ray chest, ultrasonography of abdomen and other body parts, CT, MRI and echocardiography are helpful to localize infection and evaluation of organ systems.

MANAGEMENT^{9,10}

The management of severe sepsis with evidence of circulatory, respiratory and metabolic abnormalities is best done in a pediatrics ICU by experts and is discussed in detail elsewhere in this book. However, the initial assessment and stabilization should start in any pediatrics clinic or emergency room pending transfer.

The therapeutic strategies are:

- Optimize organ perfusion (Early Goal Directed Therapy EGDT)
 - Fluid resuscitation
 - Oxygen delivery
 - Maintenance of circulatory, respiratory and metabolic alterations.

- Control infection by antibiotics and source control
- Support dysfunctional organ systems
- Modulation of host responses especially the inflammatory response which is full of controversies.
- Adjunctive therapy, e.g. glycemic, hypocalcemia control, sedation/ analgesia, stress ulcer and DVT prophylaxis and nutrition.

The nonavailability of high tech gadgets should not be a deterrent to early recognition and management of severe sepsis as strong evidence exists for dramatic reduction in mortality just by meticulous clinical monitoring of therapeutic endpoints like oxygen saturation, CVP, CRT, urine output, blood pressure and auscultation.

Empirical Antibiotic Therapy

Early antibiotic therapy preferably within one hour of diagnosis after taking the appropriate culture samples is critical for a favorable outcome. To cover the most likely organisms a combination of third generation cephalosporin, e.g. ceftriaxone and an aminoglycoside like amikacin is appropriate for community acquired sepsis. The

nosocomial infections are best treated by drugs based on the local epidemiology and available antibiograms. The source control measures like drainage, debridement and removal of foreign bodies are important if the focus of infection is amenable to such interventions.

Corticosteroids

Hydrocortisone 50 mg/ sqm/dose every 6 hours is recommended for catecholamine resistant septic shock till reversal of shock. Suspected adrenal insufficiency is another indication in pediatric sepsis. The adrenal insufficiency is likely in children with severe septic shock and purpura, history of chronic illness requiring steroids, pituitary or adrenal problems and a documented random cortisol level <18 mcg/dl. The replacement dose is 50 mg/sqm/ 24 hr. There is no recommendation for routine use of steroids in severe sepsis as it was associated with a higher mortality in a large study.¹¹

Activated Protein C

Recombinant activated protein C though has shown some improvement in sepsis induced coagulation abnormalities is not recommended in pediatric sepsis. The product has been withdrawn from the market after the PROWESS-SHOCK study.^{12,13}

Other Modalities

IVIG in severe sepsis has no strong recommendation. Stress ulcer prophylaxis by H2 blockers is widely used without any strong evidence or recommendation. ECMO is reserved for refractory septic shock and respiratory failure. DVT prophylaxis is important for postpubertal children.

The diagnosis and management of pediatric sepsis is a dynamic process and has witnessed tremendous inputs in the last two decades and shall keep evolving over the years with more evidence based recommendations. Recently, the Surviving Sepsis Campaign (SSC) guidelines have been criticized for being more opinion based rather than evidence based.¹⁴ the Australian and New Zealand intensive care society has questioned the validity of SSC guidelines and declined endorsement.^{15,16} However, the crux remains in a high index of suspicion, early diagnosis and prompt intervention with whatever resources available to have a favorable outcome in this potentially life-threatening event.

CHAPTER 42

Understanding Meningococcal Disease

Arvind Taneja

Meningococcal meningitis was first historically described in 1805 in Geneva, Switzerland. *Neisseria meningitidis* cause endemic and epidemic disease across the world including our country. The last two epidemics we had in our country were in 1986 and again in 2005 caused by serogroup 'A'. There is however a 'multicountry meningitis belt' in Sub Saharan Africa where the disease is hyper endemic due to unknown reasons and the incidence here peaks in the dry months between November and May only to subside with the onset of the Rainy season. The disease in this area is almost exclusively caused by Serogroup 'A'. Other epidemics caused by other serogroups have been described in Norway, Finland, Saudi Arabia, United Kingdom, New Zealand and Brazil. The background incidence in developing countries is 15 to 20 cases per 100,000 population per year. This increases dramatically during epidemics.

MICROORGANISM

The genus *Neisseria* has two important human pathogens *N. meningitidis* and *N. gonorrhoea*. The other species in the genus are mostly commensals like *N. lactamica*, etc. which colonize the nasopharynx but are not pathogenic. The organism is a gram-negative *Diplococcus* but may even exist as a tetrad morphologically. The adjacent sides are flattened giving it a 'kidney bean' appearance and may be encapsulated. The organism grows best on chocolate agar or blood agar in the presence of 10 percent carbon dioxide. The species differentiation is made on the basis of sugar fermentation reactions.

N. meningitidis has the ability to share DNA with other serogroups and species of *Neisseria* colonizing the nasopharynx through transfer of DNA, thus changing its morphologic characteristics such as its capsule or its virulence or its susceptibility to sulfonamides or penicillin.

Meningococci also have pili which are important in some phases of adherence to host cells, colonization and invasion. The genes that code for pili can also be turned on and off so at times the organism may not exhibit pili.

Meningococci may also exhibit phase variation through gene transfer which allows variation of the number of surface antigens including turning 'off or on' polysaccharide capsule synthesis.

Serogrouping

There are 13 serogroups of meningococci but the ones with a pathogenic potentials are A, C, Y, W-135, X and 29-E. The polysaccharide capsule protects the organism from phagocytosis, by not allowing opsonization.

Some outer membrane proteins (OMPs) functions as porins (channels for transfer of nutrients, ions, antibiotics, etc.) from the extracellular to the intracellular compartment and vice versa). Some of the OMP facilitate adhesion and invasion.

Serotyping

The serotyping of organisms is based on outer membrane Proteins (OMP's). All meningococci have either antigenic class 2 or class 3 porin B.

Subtyping

Different subtypes are based on antigenic differences in porin A.

The outer and inner cell membrane layers of *N. meningitidis* are phospholipid bilayers. These layers sandwich a layer of peptidoglycan. Lipooligosaccharide (LOS) which is similar to LOS and Lipopolysaccharide (LPS) seen in other gram-negative bacteria is associated with the outer phospholipid layer.

EPIDEMIOLOGY

Clonal strains of *Meningococcus* can transmigrate transcontinentally. Interestingly serogroup 'A' strains do not cause disease in the North America continent in spite of being episodically introduced there on many occasions.

International outbreaks by serogroup 'A' (1987) and 'W-135' (2000) strains also originated from the pilgrims congregating in Saudi Arabia at the annual Hajj pilgrimage. Some of these pilgrims returned home before falling sick leading to intra familial spread in their home country. Saudi Arabia now mandates meningococcal quadrivalent Vaccination with A, C, Y, W-135 before allowing pilgrims into their country.

Serogroup 'B' generally causes sporadic endemic disease through the epidemic in Brazil in 1974 and the current ongoing epidemic in New Zealand since 2004 are caused by this strain.

The United Kingdom has seen an epidemic of disease caused by serogroup 'C' since the late 1990's. This epidemic has been controlled by widespread vaccination with a meningococcal C conjugate vaccine given in 3 primary doses in infancy starting at age 3 months since 1999. The risk of acquiring meningococcal disease is related inversely to age, with the highest rates occurring in children less than 1 year except in epidemic situations.

Maternal transplacental IgG antibody generally protects infants in the first three months of life. In epidemics an age shift occurs with older children, adolescents and adults more commonly affected.

Nasopharyngeal carriage is the immunizing process antibody production both homologous (to same serogroup) but also heterologous (other cross reactive serogroups) is seen within two weeks of carriage. Bacteria such as *Escherichia coli* and *bacillus* which share some polysaccharide capsular surface antigens with meningococci also contribute to immunity colonization can persist for months.

Invasive disease is favored by crowding, exposure to active or passive smoking, preceding viral and Mycoplasma infections and intimate kissing with multiple partners. These predisposing factors probably explain the spurt of meningococcal disease seen in adolescents entering colleges and living in dormitories and are the reason for classifying these groups as 'high-risk'. Functional or anatomic asplenia, congenital late complement component (C5-C9) deficiencies and properdin (Alternative pathway) deficiency also predispose to invasive meningococcal infections. Acquired complement deficiencies as seen in nephrotic syndrome chronic liver disease and Systemic lupus erythematosus (SLE) also put one in the same bracket of an immune compromised host.

PATHOLOGY AND PATHOGENESIS

Encapsulated typeable meningococci are pathogenic and virulent, whereas non encapsulated strains are relatively

nonpathogenic. Meningococci adhere to non-ciliated columnar epithelial cells in the nasopharynx via pili. Binding induces endocytosis of the organism into the epithelial cell and subsequent invasion of the blood stream if anybody is insufficient.

Occasionally unsuspected bacteremia has been detected on a blood culture in a normal appearing febrile patient and this bacteremia and fever has subsequently cleared on a follow-up blood culture without antibiotics. However in most cases such clearance does not occur and the individual becomes progressively ill. Bacteria in blood may then seed the meninges or other tissues and cause meningitis arthritis, pneumonitis, etc.

Meningococci release blebs from their surface that contain outer membrane proteins laden with LOS. LOS is a potent endotoxin and concentrations of LOS correlate with the severity of disease LOS mediates release of tumor necrosis factor (TNF- α) and other host of proinflammatory and anti inflammatory cytokines.

These cytokines contributes to a procoagulant state resulting in formation of microthrombi, endothelial damage, capillary leakage and vasodilatation as seen in shock and peripheral gangrene and ARDS.

Adrenal hemorrhage is seen in 50 percent of fatal cases and necrotizing myocarditis in 75 percent of the cases.

CLINICAL MANIFESTATIONS AND DIFFERENTIAL DIAGNOSIS

The manifestations of meningococcemia and meningitis are already very well known to Pediatricians and shall not be covered in this review, since they are not really recent advances in the body of knowledge on the subject.

Skin Manifestations

Meningococcal disease cutaneous changes if present, range from diffuse mottling to diffuse extensive purpuric lesions with shock (Purpura fulminans).

Chronic Meningococcemia

Presents as a fever of unknown origin with or without chills lasting more than a week with arthralgia, petechial rashes and headaches. These patients are non toxic and the mean duration of illness before diagnosis is generally 6 to 8 weeks. Bacteremia and symptoms are intermittent and clear rapidly with antibiotic administration.

Pneumonia

Meningococci of serogroup Y are generally responsible for 90 percent of cases. Pathogenesis is thought to be through inhalation of pulmonary droplets. Isolation of organism by sputum culture is not confirmatory, only blood culture or lung fluid aspirate is diagnostic.

Arthritis

It occurs primarily in adults. Rarely it could occur secondary to bacterial seeding into synovium from a bacteremia and more commonly immune mediated arthritis due to antigen-antibody immune complexes could occur 3 to 7 days after initiation of antibiotic treatment for meningococemia since the joint fluid is often sterile.

MYOCARDITIS AND PERICARDITIS

Bacterial pericarditis occurs in less than 5 percent cases. Most symptomatic pericardial effusions develop late in the course of the illness, are serous in nature and are sterile reflecting an immune complex pathogenesis. They may be severe enough to cause cardiac tamponade.

Miscellaneous meningococcal infections include conjunctivitis, mesenteric adenitis, peritonitis and genitourinary infections.

LAB DIAGNOSIS

Meningococci have been demonstrated in a gram stain of CSF in the absence of CSF pleocytosis.

Gold standard for diagnosis is based on recovering the organism from the blood and CSF (culture), and needle aspiration of purpuric lesions (Gram stain and culture).

Latex agglutination for antigen detection on serum or urine is not recommended because of shared antigens with *E. coli*. Latex particle agglutination in CSF is useful.

Polymerase chain reaction (PCR) is one of the newer tests increasingly being used in Europe and is sensitive even in patients who have been treated with antibiotics before collecting the sample. Sensitivity and specificity of PCR is almost 90 percent.

Mortality and Prognosis

Five features are identified with a poor prognosis:

- Shock or seizures on initial evaluation
- Hypothermia
- Total WBC count less than 5000/mm³
- Platelet count less than 100,000/mm³
- Development of purpura fulminans.

Mortality is substantially higher in epidemic than in endemic disease and higher in young adolescents and also in patients who present without clinical or laboratory features suggestive of meningitis and have a rapid progression of disease.

Evidence suggest that genetic component of host cytokine production may be associated with severity of disease. Westendorp and co-workers reported that families with low TNF- α production or high IL-10

(Interleukin-10) production are at increased risk for having fatal outcomes.

TREATMENT WITH ANTIBIOTICS

Ceftriaxone is the drug of choice and the first dose should be administered as soon as possible after a presumptive diagnosis is made. In dire emergent situations it is perfectly justified in giving the 1st dose of IM Ceftriaxone in the Pediatric office even before transporting the patient to the hospital since the doubling time of the bacteria is 20 minutes and bacterial load can build up dramatically affecting ultimate prognosis.

EXPERIMENTAL AND ADJUNCTIVE THERAPIES

Infusion of activated protein C concentrate (Xigris) found favor a few years ago based on initial clinical trials in adults but subsequent data in pediatric trials do not support its use since it does not reduce mortality rates and in fact may increase DIC and bleeding manifestations.

Two antiendotoxin therapies have been evaluated in clinical trials in the year 1999 and 2000. These are HA-IA (human monoclonal antibody) and recombinant bactericidal/permeability increasing protein (rBPI).

The beneficial effect of neither of the therapies achieved statistical significance.

Prophylactic low dose heparin has also been used but it is very difficult to monitor the dosage leading to over dosage and toxic effects. Caudal block has been used to restore lower extremity perfusion in gangrene.

Chemoprophylaxis

Since the secondary attack rate is very high in the 96 hr after detection in the index case, this modality is indicated to reduce nasopharyngeal carriage in intimate contacts at home (living under the same roof), day care centre or crèche or same section of the class at school. Incidental exposure on the playground or in the school bus lasting less than an hour or two does not constitute intimate contact and does not necessitate chemoprophylaxis.

The index patient should also receive chemoprophylaxis before discharge home to eliminate nasopharyngeal carriage, especially if the therapeutic antibiotic chosen was not ceftriaxone/ cefotaxime but penicillin or Sulfonamide or Chloramphenicol.

All contacts given chemoprophylaxis should also receive meningococcal vaccine (with the realization that there is no effective vaccine against serogroup B disease.

The various regimes used for chemoprophylaxis are given in Table 1.

Table 1: Various regimes used for chemoprophylaxis

Drug	Age	Dose/Duration
Rifampin	Adults	P.O. 600 mg twice daily x 4 doses (Max daily dose 600 mg.)
	Children >1 month	P.O 10mg/kg/ dose twice daily x 4 doses (Max daily dose 600 mg)
	Babies <1 month	P.O 5 mg/kg/ dose twice daily x 4 doses
Ceftriaxone	Children >15 yrs	IM 250 mg single dose
	Children <15 Yrs	I/M 125 mg single dose
Ciprofloxacin	Adults	P.O. 500 mg single dose
	Children	P.O. 10mg/kg single dose (Not to exceed 500 mg)
Azithromycin	Adults	P.O 500 mg single dose
	Children	P.O 10 mg/kg single dose

MENINGOCOCCAL VACCINE

Two kinds of vaccines are available. Meningococcal polysaccharide vaccine (MPSV) and meningococcal conjugate vaccine (MCV).

The polysaccharide vaccine is poorly immunogenic in children below 2 years of age and shows the phenomena of immune tolerance i.e. hyporesponsiveness of antibody production when booster doses are administered specially in children below 5 yrs of age. These vaccines do not elicit immunological memory, i.e. are T-cell independent and booster doses are recommended every 3 years. Immunity induced by group A vaccine given below 24 months of age is poor and immunity with group C vaccine in this age group is nonexistent. These vaccines are administered subcutaneously.

In our country routine childhood vaccination schedule till the age 12 yr does not recommend meningococcal vaccine except in exceptional circumstances like an ongoing epidemic, complement or properdin deficiency, functional or anatomic asplenia or travel to a hyperendemic zone such as the meningitis belt of sub saharan Africa. This vaccine is much less expensive than the conjugate vaccine.

The MCV4 quadrivalent conjugate vaccine (Menactra) is to be introduced by aventis this country in the next year and induces immune memory since it is T-cell dependent but is expected to cost around Rs. 5000/- a dose. It utilizes the same technology as the HIB vaccine since it binds the purified capsular polysaccharide to the CRM 197 component of the diphtheria toxoid which acts as its protein carrier. It is administered intramuscularly.

Encouraging trials are ongoing on its effectivity below 2 yr of age and current recommendations recommend a booster dose 3 to 5 years later to maintain ongoing immunity. It is the vaccine of choice to be given to adolescent populations and adults.

In response to an ongoing epidemic of meningococcal serogroup B disease in Northern New Zealand especially among the "Maori" a new vaccine has been formulated by Novartis in 2007 by using the outer membrane vesicle and this vaccine has helped considerably in controlling the epidemic.

Similarly in response to the UK and Irish epidemic a group C-conjugate vaccine has been in use and has effectively controlled the spread of the disease.

CHAPTER 43

Poliomyelitis

Raju C Shah, Rekha Luthra, Anupam Sachdeva

INTRODUCTION

Poliomyelitis is an acute infectious disease of humans, particularly children caused by any of three serotypes of human poliovirus.

Persons at risk of polio—*Polio mainly affects children under 5 years of age.*

Polio caseload—Polio cases have decreased by over 99 percent since 1998, from estimated more than 35,000 cases to 871 cases in 2007, 559 cases in 2008, 740 cases in 2009, 42 cases in 2010 and only 1 case of wild polio till 21st November 2011. The reduction is the result of the global effort to eradicate the disease.

HISTORY

Poliomyelitis, the first enteroviral disease to be recognized and the most important one, has a long history.¹ The earliest record is an Egyptian stele of the 18th dynasty (1580 to 1350 BC), which shows a young priest with a withered, shortened leg, the characteristic deformity of paralytic poliomyelitis.^{2,3} Michael Underwood,⁴ a London pediatrician, published the first medical description in 1789 in *A Treatise on Diseases of Children*. During the 19th century, many reports appeared in Europe and the United States describing small clusters of cases of “infantile paralysis.” The authors were puzzled about the nature of the affliction; not until the 1860s and 1870s was the spinal cord firmly established as the seat of the pathologic process. The contagious nature of poliomyelitis was not appreciated until the latter part of the 19th century. Medin, a Swedish pediatrician, was the first to describe the epidemic nature of poliomyelitis (1890), and his pupil Wickman worked out the basic principles of the epidemiology.⁵

The virus first was isolated in monkeys by Landsteiner and Popper in 1908.⁶ The availability of a laboratory animal assay system opened up many avenues of research

that in the ensuing 40 years led to the demonstration that an unrecognized intestinal infection was the usual one and the paralytic disease a relatively uncommon event (Figs 1 and 2).

THE VIRUS

Morphology and Classification⁷⁻¹³

The enteroviruses (coxsackie viruses, echoviruses, polioviruses and newer enteroviruses and paraechoviruses) are single-stranded RNA viruses belonging to the family Picornaviridae (pico = small). They are grouped together because they share certain physical, biochemical, and molecular properties. On electron micrographs, the viruses are seen as 30-nm particles that consist of naked protein capsids constituting approximately 70 to 75 percent of the particles and dense central cores (nucleoloid) of RNA. Enterovirus capsids are composed of four structural proteins: VP1, VP2, VP3, and VP4. The shell is formed by VP1, VP2, and VP3; VP4 is on its inner surface.

The coat proteins protect the RNA genome from nucleases and are important determinants of host range and tropism. They determine antigenicity and they deliver the RNA genome into the cytoplasm of new host cells.

The genome of enteroviruses is a single-stranded, positive-sense RNA molecule.¹

Viral components and complete virions are formed in the cytoplasm of infected cells.

Characteristics and Host Systems^{8,15,16}

Enteroviruses are relatively stable viruses in that they retain activity for several days at room temperature and can be stored indefinitely at ordinary freezer temperatures (– 20°C). They are inactivated quickly by heat (>56°C), formaldehyde, chlorination and ultraviolet light.

Fig. 1: Monthly incidence of polio in India (January 1998–September 2005) (For color version see plate 4)

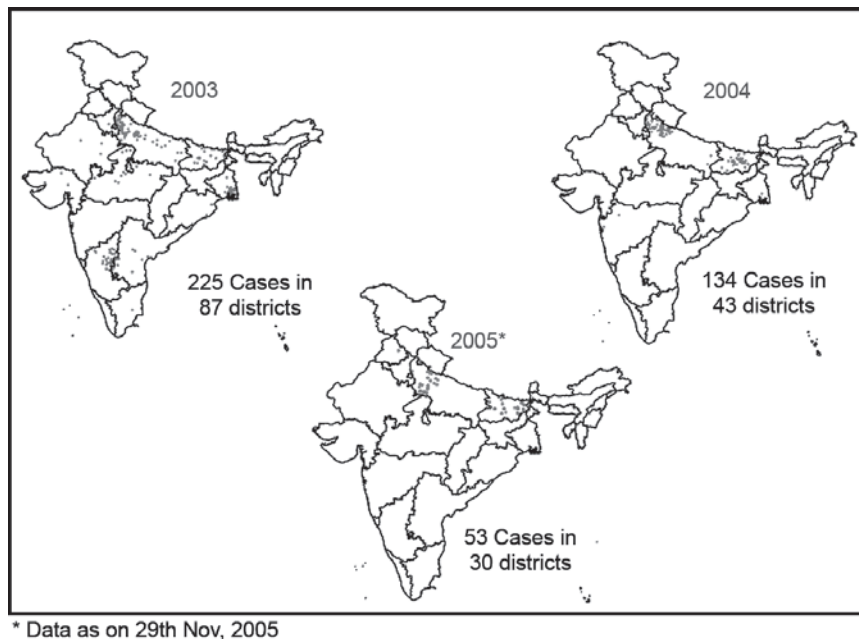

Fig. 2: Location of poliovirus, India 2003–2005 (For color version see plate 4)

Enteroviral strains grow rapidly when adapted to susceptible host systems and cause cytopathology in 2 to 7 days.

Unadapted viral strains frequently require long periods of incubation.

Host Range

Humans are the only natural hosts of polioviruses.

Epidemiology

Transmission

Humans are the only natural hosts of human polioviruses;^{17–24} spread is from person to person by the fecal oral route and possibly the oral-oral (respiratory spread) route. Children are the main susceptible cohort; they are immunologically susceptible, and their unhygienic habits

facilitate spread. Spread is from child to child (via feces to skin to mouth) and then within family groups. Recovery of enteroviruses is related inversely to age, but the prevalence of specific antibodies is related directly to age. The incidence of infection and the prevalence of antibodies do not differ between boys and girls.

Geographic Distribution and Season

Enteroviruses have a worldwide distribution.²⁵⁻²⁷ In any given area, frequent fluctuations occur in predominant types. Epidemics probably depend on newly susceptible individuals in the population rather than reinfection; they may be localized and sporadic and may vary in etiology from place to place in the same year. In temperate climates, enteroviral infections occur primarily in the summer and fall, but in the tropics, they are prevalent all year.^{18,25,27,28}

Pathogenesis and Pathology

Events During Pathogenesis^{8,16,25,29-31}

In Flow chart 1 events of pathogenesis. After initial acquisition of virus by the oral or respiratory route, attachment to the cellular receptor (PVR) takes place. After attachment replication cycle takes 5 to 10 hours and occurs in the cytoplasm, implantation occurs in the pharynx and the lower alimentary tract. Within 1 day, the infection extends to the regional lymph nodes. On approximately the third day, minor viremia occurs and results in the involvement of many secondary infection sites.

Multiplication of virus in secondary infection sites coincides with the onset of clinical symptoms. Illness can vary from minor infections to fatal ones. Major viremia occurs during the period of multiplication of virus in secondary infection sites; this period usually lasts from the third to the seventh day of infection.

Cessation of viremia correlates with the appearance of serum antibody. The viral concentration in secondary infection sites begins to diminish on approximately the seventh day. However, infection continues in the lower intestinal tract for prolonged periods.

In Figure 3, clinical and subclinical events in polioviral infections are presented. By 3 to 5 days after exposure, virus can be recovered from blood, the throat and feces. This finding may be accompanied by symptoms of the “minor illness,” or the infection may be unrecognized clinically. The end of the period of viremia coincides with the appearance of antibodies and the onset of clinical signs of CNS involvement. The available evidence factors blood as the main pathway of CNS invasion in natural disease but experimental infections in monkeys indicate that the virus can travel along the axons of peripheral nerves. Possibly, when tonsillectomy is performed on a child with inapparent poliovirus infection, the virus enters the nerve fibers exposed during surgery and spreads to the cranial nerve nuclei in the brain, thereby resulting in bulbar paralysis.

Flow chart 1: Pathogenesis of enteroviral infections (Modified from Cherry JD: Enteroviruses. In Remington JS, Klein JO (Eds): Infectious Disease of the Fetus and Newborn Infant. Philadelphia: WB Saunders, 1976

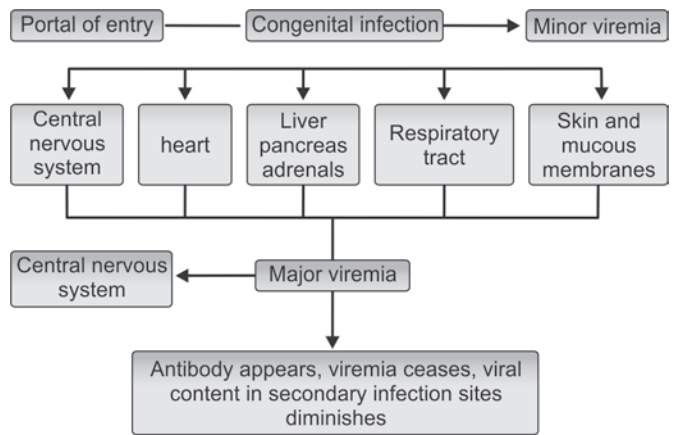

Fig. 3: The course of clinical and subclinical forms of poliovirus infection in relation to the presence of virus and the development of antibodies (From Bodian D and Horstmann D/M Poliomyelitis. In Horsfall FL and TAM I (Eds). Viral and Rickettsial Infections of Man (4th edn.) Philadelphia, JB Lippincott 1965;430-73)

Factors that Affect Pathogenesis

The pathogenesis and pathology of enteroviral infections depend on the virulence, tropism and inoculum concentration of virus, as well as on many specific host factors. Enteroviruses have marked differences in both tropism and virulence. Although some generalizations can be made with regard to tropism, marked differences occur even among strains of specific viral types. Differences in the virulence of specific enteroviral types may be the result of recombination among enteroviruses or point mutations.³²⁻³⁴

Van Eden and Associates³⁵ studied 17 families during an outbreak of poliomyelitis caused by type 1 virus in the Netherlands and their findings suggested that HLA-related genetic factors were important in the occurrence of paralytic disease.

In the past, researchers assumed that specific pathology in various organs and tissues in enteroviral infections was caused by the direct cytopathic effect and tropism of a particular virus. In more recent years, however, a large number of studies using murine model systems have suggested that host immune responses contribute to the pathology. These studies suggest that T cell-mediated processes and virus-induced autoimmunity cause both acute and chronic tissue damage. In contrast, other studies suggest that the primary viral cytopathic effect is responsible for the tissue damage and that the various T cell responses are a reaction to the damage and not the cause of the damage.³⁶

Pathology^{29,37}

The neuropathy of poliomyelitis usually is pathognomonic; only certain cells and areas of the neuraxis are susceptible to the virus. Neuronal damage is caused directly by virus multiplication but not all affected neurons are killed. The injury may be reversible and function may be restored within 3 to 4 weeks after onset. Little histologic evidence of meningeal reaction exists. Perivascular cuffing and some interstitial glial infiltration is present. Histologic sections generally reveal more widespread lesions than would be estimated from the clinical findings. Scattered neurons may undergo considerable destruction without clinical disability.

Regions in which neuronal lesions occur are:

- The spinal cord (anterior horn cells chiefly and to a lesser degree the intermediate and dorsal horn and dorsal root ganglia)
- The medulla (vestibular nuclei, cranial nerve nuclei, and the reticular formation that contains the vital centers)
- The cerebellum (nuclei in the roof and vermis only)
- The midbrain (chiefly the gray matter but also the substantia nigra and occasionally the red nucleus)
- The thalamus and hypothalamus
- The pallidum
- The cerebral cortex (motor cortex). The viruses spare the following areas:
 - The entire cerebral cortex except the motor area,
 - The cerebellum except the vermis and deep midline nuclei
 - The white matter of the spinal cord. This distribution of lesions permits a histological diagnosis of poliomyelitis.

Extraneural pathology usually is a secondary phenomenon. Bronchopulmonary changes such as aspiration

pneumonia, atelectasis and purulent bronchitis may occur because of impaired coughing and decreased thoracic movement. Cardiovascular changes may result in hypertension, cardiac failure and pulmonary edema. Prolonged immobilization leads to negative nitrogen and calcium balance along with urinary lithiasis, renal failure, hypertension with encephalopathy and convulsions. Treatment itself may cause untoward complications, such as urinary tract infection after catheterization, decubitus ulcers and psychotic disturbances. Ulcerations in the alimentary tract may result in serious bleeding and occasional perforation. Respiratory failure culminates in respiratory acidosis and anoxic changes.

Clinical Manifestations^{29,30,37,39,41}

When a susceptible person has had effective contact with a poliovirus, one of several responses may occur in the following order of frequency:

- Inapparent infection
- Minor illness (abortive poliomyelitis)
- Nonparalytic poliomyelitis (aseptic meningitis)
- Paralytic poliomyelitis.

Paralytic poliomyelitis is the most dramatic expression of the infection and the only one clinically recognizable as caused by a poliovirus; it accounts for not more than 1 to 2 percent of infections during epidemics and considerably less under endemic conditions. The aseptic meningitis syndrome is similarly infrequent; nonspecific “minor illness” is estimated to occur in 4 to 8 percent and 90 to 95 percent of those infected have in apparent infections. Factors that determine the type of clinical response are poorly understood but the degree of virulence of the virus and certain host characteristics are important.

Age has a significant effect on patterns of infection; older patients are more likely to have severe paralytic disease and a higher mortality rate. Tonsillectomy in the presence of inapparent infection can precipitate bulbar poliomyelitis; evidence also suggests that tonsillectomy at any time in the past results in enhanced susceptibility to the bulbar form of the disease. Recent diphtheria-tetanus-pertussis vaccination increases the likelihood of development of paralysis; the site of injection and the site of paralysis appear to be correlated. Physical exertion and trauma around the time of onset also increase the risk for severe paralysis.

Minor Illness (Abortive Poliomyelitis)

The minor illness is mild and nonspecific with low-grade fever, malaise, anorexia, and sore throat. Physical examination reveals no significant abnormalities, CSF is normal, and recovery occurs within 24 to 72 hours. The illness often is so mild that it goes unrecognized and patients rarely are seen by a physician.

Nonparalytic Poliomyelitis (Aseptic Meningitis)

The onset of nonparalytic poliomyelitis is associated with vague malaise followed by fever, headache, aching of the muscles and sometimes hyperesthesia and paresthesia. Anorexia, nausea, vomiting, constipation, or diarrhea may also be present. The temperature rises to 37.8° to 39.5°C (101° to 103°F); stiffness of the neck, back, and hamstrings soon appears.

Approximately, two-third of affected children have a short symptom-free interlude between the first phase (minor illness) and the second phase (CNS or major illness). Nuchal and spinal rigidity is necessary for the diagnosis of nonparalytic poliomyelitis during the second phase.

Physical examination reveals nuchal-spinal signs and changes in superficial and deep reflexes. With cooperative patients, the nuchal-spinal signs are sought first by active tests. The child is asked to sit up unassisted. If doing so causes undue effort, if the knees flex upward, and if the patient writhes a bit from side to side while sitting up and uses the hands on the bed for the tripod supporting position, unmistakable spinal rigidity is present. Still sitting, the patient is asked to flex chin to chest and is observed for nuchal rigidity. Alternatively, from the supine position with the knees held down gently, the patient is asked to sit up and kiss the knees. If the knees draw up sharply or if the maneuver cannot be completed adequately, the patient has stiffness of the spine caused by muscle spasm. If the diagnosis still is uncertain, attempts should be made to elicit the Kernig and Brudzinski signs. Gentle forward flexion of the occiput and neck elicits nuchal rigidity, which may precede spinal rigidity. Head drop may be demonstrated by placing the hands under the patient's shoulders and raising the trunk. Normally, the head follows the plane of the trunk but in poliomyelitis, it often falls backward limply. The frequency of the head-drop sign, even in nonparalytic poliomyelitis, with no subsequent residuals indicates that it is not caused by true paresis of the neck flexors. In struggling infants, distinguishing voluntary resistance from clinically important involuntary nuchal rigidity may be difficult. One may place the infant's shoulders flush with the edge of the table, support the weight of the occiput in the hand and then flex the head anteriorly. Nuchal rigidity that persists during this maneuver may be interpreted as involuntary. When not closed, the anterior fontanel also may be tense or bulging.

In the early stages, the reflexes are normally active and remain so unless paralysis supervenes. Changes in reflexes, either increased or depressed may precede weakness by 12 to 24 hours; hence, detecting such changes is important, especially in nonparalytic patients managed at home. The superficial reflexes (i.e. cremasteric and abdominal and the reflexes of the spinal and gluteal muscles) are usually the first to be diminished. The spinal and gluteal reflexes are elicited by tapping segmentally downward on each side

of the spine and buttocks. These reflexes may disappear before the abdominal and cremasteric ones do. Changes in the deep tendon reflexes, whether exaggerated or depressed, generally occur 8 to 24 hours after depression of the superficial reflexes and indicate impending paresis of the extremities. If no further progression of clinical signs occurs, the disease remains nonparalytic, the temperature falls to normal, and signs of meningeal irritation gradually disappear. Recovery ensues in 3 to 10 days, depending on the severity of the illness.

Paralytic Poliomyelitis

The manifestations of paralytic poliomyelitis are those enumerated earlier for nonparalytic poliomyelitis plus weakness in one or more muscle groups, either skeletal or cranial. Patients in whom paralysis is destined to develop often wear an anxious expression; they are extremely alert, restless, and flushed and appear acutely ill. The fever is higher than that in abortive disease, and the patient may have intense muscle pain. Shortly, before actual muscle weakness is detected, the superficial and deep reflexes often diminish or disappear on the affected side. Frequently, a symptom-free interlude of several days occurs between the initial illness phase and the recurrence of symptoms that culminate in paralysis.

The onset of paralysis may be extraordinarily sudden and progress in a few hours to complete loss of motion in one or more extremities. Asymmetric involvement is typical in milder cases. More gradual spread of weakness also occurs and may continue over a period of 3 to 5 days. Bladder paralysis of 1 to 3 days' duration develops in approximately 20 percent of patients and bowel atony is noted commonly, occasionally to the point of paralytic ileus. In general, when the fever subsides, no further paralysis is likely to occur. The lower limbs are affected more commonly than are the upper, but in severe cases, quadriplegia and loss of function of the intercostals, abdominal, and trunk muscles with resultant respiratory difficulty may ensue. The superficial and deep reflexes in the affected limbs are lost; twitching of the muscles and diffuse fasciculation may be seen transiently. Sensory abnormalities are rare occurrences.

Flaccid paralysis is the most obvious clinical expression of the neuronal changes. The ensuing muscular atrophy is caused by denervation plus the atrophy of disuse. The pain, plasticity, nuchal and spinal rigidity, and hyper-tonia early in the illness probably are caused by lesions in the brainstem, spinal ganglia, and posterior columns. Respiratory and cardiac arrhythmias, blood pressure and vasomotor changes, and the like reflect damage to vital centers in the medulla.

On physical examination, the distribution of paralysis characteristically is spotty. To detect mild muscular weakness, one often must apply gentle resistance in opposition to the muscle group being tested. The spinal form has

weakness of some of the muscles of the abdomen, trunk, diaphragm, thorax, or extremities. The bulbar form is characterized by weakness in the motor distribution of one or more cranial nerves, with or without dysfunction of the vital centers of respiration and circulation. Patients with bulbar disease often are extremely agitated, even delirious, or they may become stuporous. The 10th cranial nerve nuclei are involved most commonly and result in paralysis of the pharynx, soft palate, and vocal cords. Facial paralysis occurs less commonly; it is usually asymmetric and involves only selected muscle groups. Ocular palsies are unusual findings.

Components of both the bulbar and spinal forms occur together in bulbospinal poliomyelitis. In the encephalitic form of the disease, irritability, disorientation, drowsiness, and coarse tremors not explained by inadequate ventilation are noted. Even during poliomyelitis epidemics, this form can be recognized only if some peripheral or cranial nerve paralysis coexists or ensues. Hypoxia and hypercapnia caused by inadequate ventilation from respiratory insufficiency may produce disorientation without true encephalitis.

Numerous components acting together may result in insufficiency in ventilation. The most serious consequences are hypoxia and hypercapnia, which may produce profound effects on many other systems. Respiratory insufficiency should be detected early to diminish its widespread effects, and because the situation may shift rapidly, continued clinical evaluation is essential. Despite weakness of the respiratory muscles, the patient may respond with so much respiratory effort that normal alveolar ventilation is maintained. In fact, the increased effort (associated with anxiety and fear) actually may produce over ventilation at the outset and result in respiratory alkalosis. Such effort is fatiguing and soon leads to respiratory failure.

Diagnosis

Clinical Diagnosis

As with all infectious illnesses, knowledge of exposure, incubation time and clinical features is important. Vaccine associated paralytic poliomyelitis (VAPP) should be considered in any child with paralytic disease occurring 7 to 14 days after receiving OPV (and at later times in countries where wild poliovirus has been eradicated and OPV has been administered to the child or a contact.)

Laboratory Diagnosis

CSF is normal in minor illness.

In non-paralytic poliomyelitis (aseptic meningitis), laboratory findings consist of a normal or slightly elevated white blood cell count and the characteristic CSF changes of aseptic meningitis: Approximately 20 to 300 cells, predominantly lymphocytes, a normal glucose level and normal or slightly elevated protein. If a spinal tap is

performed in the first few hours after onset, a predominance of polymorphonuclear leukocytes may be seen but it shifts in 6 to 12 hours to more than 90 percent lymphocytes.

Virus Isolation and Detection Techniques

Most viral diagnostic laboratories have facilities for the recovery of most enteroviruses that cause illness. WHO currently recommends that the laboratory diagnosis of poliomyelitis be confirmed by isolation and identification of wild type and vaccine type strains in the stool. Polioviruses can be separated from other enteroviruses and poliovirus vaccine strains can be identified rapidly by PCR,⁴² along with the wild poliovirus as well.

Treatment

Specific Therapy

No specific therapy for any enteroviral infection presently is approved for use. The antiviral drug pleconaril offers promise for the treatment of enteroviral infections.⁴³⁻⁴⁶ This drug is a novel compound that integrates into the capsid of enteroviruses. It prevents the virus from attachment and subsequent release of viral RNA into the host cell. In a double-blinded, placebo-controlled study of 39 patients with enteroviral meningitis, a statistically significant shortening of disease duration was noted: From 9.5 days in controls to 4.0 days in drug recipients.⁴⁵ Pleconaril also has been used on a compassionate-release basis for the treatment of patients with life-threatening infection.⁴⁶ The following categories of enteroviral illnesses have been treated; chronic meningoencephalitis in patients with agammaglobulinemia or hypogammaglobulinemia, neonatal sepsis, myocarditis, poliomyelitis (wild type or vaccine associated), encephalitis and bone marrow transplant patients. Although these treatments have not had control arms, favorable clinical responses have been observed in 22 of 36 treated patients, including 12 of 18 patients with chronic meningoencephalitis.

Nonspecific Therapy (Mild, Nonspecific Febrile Illness)

In patients in whom fever is the only symptom, careful observation is important. Many patients who eventually become severely ill initially have 2 to 3 days of fever without other localized findings. Care should be taken to administer adequate fluids to febrile infants, and excessive elevation of temperature should be prevented if possible.

Meningoencephalitis

In patients with meningoencephalitis, convulsions, cerebral edema and disturbances in fluid and electrolyte balance, all occur frequently and respond to treatment. Seizures are treated best with phenobarbital, phenytoin, or Lorazepam. Cerebral edema can be treated with urea,

mannitol. Fluids should be monitored closely, and serum electrolyte levels should be determined frequently because inappropriate antidiuretic hormone secretion is a common occurrence.

Management of Poliomyelitis

The broad principles of management are to allay fear, minimize the ensuing skeletal deformities, anticipate and meet complications in addition to the neuromusculoskeletal ones, and prepare the child and family for the prolonged treatment that may be required and for permanent disability when it seems likely. Patients with the nonparalytic and mildly paralytic forms may be treated at home.

Worldwide Cases of Poliomyelitis.

Most patients with paralytic poliomyelitis require hospitalization. A calm atmosphere is desired. Suitable body alignment is necessary to avoid excessive skeletal deformity. A neutral position with the feet at a right angle, knees slightly flexed and hips and spine straight is achieved by the use of boards, sandbags and occasionally, light splint shells. Active and passive motion is indicated as soon as the pain has disappeared. The orthopedist and physiatrist should see these patients as early in the illness as possible and assume responsibility before fixed deformities develop.

Management of pure bulbar poliomyelitis consists essentially of maintaining the airway and avoiding all risks of inhalation of saliva, food, or vomitus. Gravity drainage of accumulated secretions is favored by the head-low (foot of the bed elevated 20 to 25 degrees) prone position with the face to one side. Aspirators with rigid or semirigid tips are preferred for direct oral and pharyngeal use and soft flexible catheters may be used for nasopharyngeal aspiration. Fluid and electrolyte balance is maintained best by intravenous infusion because tube or oral feeding in the first few days may incite vomiting. After the initial few days, sips of sterile water may be given from a spoon, with increments as indicated by the ability to swallow. In addition to close observation for respiratory insufficiency, blood pressure should be recorded at least twice daily. Hypertension is not an uncommon occurrence and occasionally leads to hypertensive encephalopathy. Patients with pure bulbar poliomyelitis may require tracheostomy because of vocal cord paralysis or constriction of the hypopharynx. Most patients with pure bulbar poliomyelitis who recover have little residual impairment; some patients exhibit mild dysphasia and occasional vocal fatigue with slurring of speech.

Impaired ventilation must be recognized early; mounting anxiety, restlessness, and fatigue are early indications for prompt intervention. Tracheostomy is indicated for some patients with pure bulbar poliomyelitis, spinal respiratory muscle paralysis, and bulbospinal paralysis. Unlike other patients on whom tracheostomy is performed, these patients generally are unable to cough, sometimes for many months. Frequent and swift endotracheal aspiration

under aseptic conditions is necessary. Mechanical ventilation often is needed. Patients are fully conscious and aware; terrifying procedures are performed best with an outward atmosphere of calm. Explaining the procedure and having the parents on hand may be helpful. A reduction in thoracic compliance occurs early, and higher than expected pressure gradients may be required to achieve adequate ventilation. Weaning a patient from dependency on respiratory assistance is a torturous process, as is total musculoskeletal rehabilitation. Motivation of the patient and the team of personnel are paramount.

Prognosis: The prognosis for poliomyelitis varies with the degree of muscle involvement. In patients with mild muscle weakness, complete recovery is the rule. If paralysis is present, recovery of muscle function continues for a period of approximately 18 months to 2 years. By 3 months, about 60 percent of the ultimate improvement has been achieved, and by 6 months, 80 percent. The final result depends on the extent and localization of nerve cell damage.

Respiratory failure is responsible for most of the deaths in paralytic poliomyelitis. With the many recent improvements in techniques for handling this complication, the overall mortality rate has been reduced to approximately 4 percent.

Occasionally, new neuromuscular symptoms develop later in life in patients who have had paralytic poliomyelitis.⁴⁷⁻⁵⁴ Although the cause of this late-onset weakness and muscle atrophy (post-polio syndrome) is not understood completely, it is most likely the result of routine attrition of anterior horn cells associated with aging rather than persistent neural infection with polioviruses. However, specific immunopathologic mechanisms possibly play a role in some instances.⁵⁵

Leparc-Goffart and associates,⁵⁶ presented data suggesting the presence of poliovirus-specific genomic sequences in the CSF of patients with post-polio syndrome. However, Muir and colleagues,⁵⁷ who performed similar studies, found no association of chronic neurologic disease with the presence of enteroviral RNA in CSF.

Prevention: There is no cure for polio, it can only be prevented. Polio vaccine, given multiple times, can protect a child for life.

THE GLOBAL POLIO ERADICATION INITIATIVE

The Global Polio Eradication Initiative is spearheaded by WHO, Rotary International, the US Center for Disease Control and Prevention (CDC) and UNICEF. This is the largest public health initiative the world has ever known. Since 1988, some two billion children around the world have been immunized against polio, thanks to the unprecedented cooperation of more than 200 countries and 20 million volunteers, backed by an international investment of US\$3 billion (Figs 4 and 5).

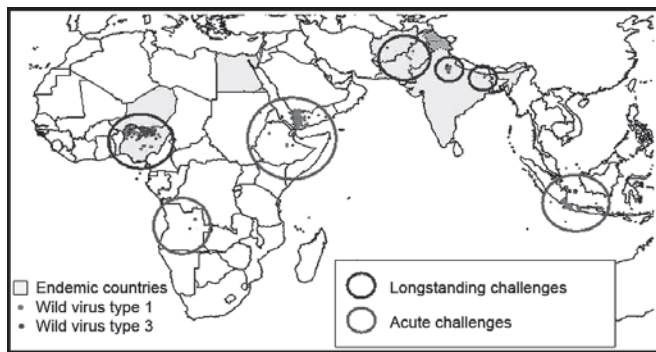

Fig. 4: Worldwide cases of poliomyelitis

Data in WHO HQ, Oct. 2005

Fig. 5: Wild Poliovirus since 1 June 2005
(For color version see plate 4)

The Progress Made

From approximately more than 3.5 lacs cases of wild polio virus from 125 countries across five continents in 1988 to only 1352 cases in 2010 and 520 cases in 2011 till 15th November. They are confined to only five key hot spots in six endemic countries representing a greater than 99 per cent reduction in number of wild poliovirus- the progress made by the eradication initiative is indeed awesome.

The Milestones

- 1991—Last case of polio in America (Peru)
- 1997—Last case of polio in Western Pacific (Cambodia)
- 1998—Last case of polio in Europe (Turkey)

The America, Europe and western pacific regions of the World Health Organization were certified polio-free in 1994, 2000 and 2002 respectively. More than three billion people now live in 134 countries and territories certified polio-free.

Fig. 6: Location of poliovirus, as on 21st November 2011*
(1 case)

Current Status

Poliovirus is more geographically restricted than ever before in history. In 2010, only six countries remained polio-endemic. More than 75 percent of all polio cases worldwide linked to just five key polio hot spots within these countries: Kano (Nigeria), Uttar Pradesh and Bihar (India) and Sindh and North west frontier province (Pakistan).

Importations of poliovirus from endemic to polio-free areas threaten to derail efforts to contain the virus. In the 2002 to 2003 period, for the first time in history, more countries suffered polio cases due to importations than were themselves endemic for the disease.

Indian Scenario

Within India, the greatest risk was in western Uttar Pradesh and Bihar, the only area of India that had never stopped wild poliovirus transmission till 2010 (Fig. 6).

India presents the greatest opportunity for success or failure in stopping polio transmission in 2011. In last two years, India dramatically increased the quantity and quality of its large-scale immunization campaigns. As a result, India now has the lowest-ever levels of poliovirus transmission in the country including two key polio hot spots of Uttar Pradesh and Bihar.

CURRENT SITUATION OF POLIO ERADICATION IN INDIA

Key Findings

- In 2010, total of 42 cases of WPV were reported from total of 4 states all over the country out of which 2 states had imported cases.

Fig. 7: Wild polio cases by age, 2003-2005*

Fig. 8: OPV status of AFP cases, India, 2005*

- Paralytic polio cases were due to P-3 WPV (24 cases) and P-1 WPV (18 cases).
- In the year 2011 till 21st November not a single case of WPV from both the hot states - UP and Bihar.
- P2 WPV is no more in India (last case in Oct 1999).
- In year 2005
 - Majority of the cases (62%) were below 24 months of age (Fig. 7).
 - Community wise break up of WPV Cases: All India cases–52 percent Muslims–48 percent Hindu; (In UP: 58% Muslims, 42% Hindu, in Bihar: 46% Muslims, 54% Hindu).
 - OPV status of WPV cases: Only 9 percent of WPV cases had received 3 or less than 3 doses (Fig. 8).
 - The OPV3 immunization status of children with AFP aged <5 years had substantially improved nationally (98% more than 3 doses), also in most of the North Indian states, particularly in UP and Bihar.

Typical Polio Cases in 2005

- Less than 2 years of age
- Had received >3-4 doses of OPV
- Religious difference narrowed down.

Vaccines Against Poliomyelitis

Raju C Shah, Rekha Luthra, Anupam Sachdeva

INTRODUCTION

There are two types of polio vaccine.

The Salk vaccine (inactivated polio vaccine, IPV) was developed by Dr Jonas Salk in 1955. It consists of injections of dead (inactivated) polio virus.

The Sabin vaccine oral polio vaccine OPV was developed more recently. This vaccine contains weakened, live virus. It is a liquid that is given by mouth. The trivalent form (TOPV) is effective against all known forms of polio; the monovalent form (MOPV) is effective against one type of polio. Oral polio vaccine is no longer used routinely in the United States.

Oral polio vaccine (OPV) is a suspension of over 1 million particles of poliovirus types 1, 2 and 3. It is supplied with a stabilizing agent, magnesium chloride. It is quite stable under refrigeration.

IPV is formaldehyde-killed poliovirus grown in monkey kidney cells/ human diploid cells containing 20, 8 and 32 antigen units of types 1, 2 and 3 respectively. Enhanced potency IPV (eIPV) that is now available contains 40, 8 and 32 antigen units.

Available Forms

OPV is available as vial containing multi doses, usually 25 doses in ready to use liquid forms. It is a live vaccine. The dose is 2 drops per dose. IPV is available as a single dose vial containing 0.5 ml of vaccine. It is also available as combination vaccines containing IPV + DPT or IPV + DPT + Hepatitis B or IPV + DPT + Hib or IPV + DPT + Hepatitis B + Hib or in combination with DPaT. IPV is now available in India.

Storage

Both OPV and IPV are to be stored in a refrigerator. OPV stocks can be stored frozen; working vials should be stored

at 2 to 8°C in the chiller tray. Once thawed it should not be frozen again as repeated freezing and thawing decreases the potency. Being a live and thermolabile vaccine strict cold chain should be maintained while transporting the vaccine. In the field, the OPV vial in use should be kept on ice. Once a vial is opened, the balance should be discarded and not used again. Nowadays vaccine vial monitors (VVM) are available which change color when subjected to a fixed hours of cumulative exposure to more than 8°C.

OPV is a pink colored solution. It may turn yellow due to changes in pH of vaccine. Such discolored vaccine or presence of visible turbidity in the vaccine is suggestive of growth of bacteria or fungi. Such vaccines should be discarded.

Schedule

OPV is given as 2 drops per orally. The first dose is given at birth – 15 days as zero does OPV. Next 3 primary doses are given at 4 weeks interval starting at 6 to 8 weeks of age. It is given along with 3 primary doses of DPT. Indian Academy of Pediatrics recommends a 5th primary dose at 9 months along with measles vaccine.

Routine Immunization of Infants

All infants should receive a minimum of four doses of oral polio vaccine OPV during their first year of life. Routine immunization provides a basic level of immunity against polio. High routine immunization coverage also reduces the amount of circulating wild poliovirus, thus facilitating eradication.

Supplementary Immunization

National immunization day is a mass campaign that aims to deliver two doses of OPV to all children aged less than five years in an entire country, on a subnational immunization

day (SNID) the same approach is used in a large area of a country. All children are immunized regardless of their prior immunization status. The two rounds are approximately a month apart and are normally conducted during the cool dry season in order to facilitate the logistics and improve the immune response to vaccination. NID's rapidly increase population immunity, particularly intestinal secretory IgA, to high levels that interrupt the circulation of wild polioviruses.

When is the Booster Dose of OPV Given?

Additional dose of OPV popularly known as booster dose of OPV is recommended by Govt. of India under EPI at 15 to 18 months of age along with the 1st booster dose of DPT. Indian Academy of Pediatrics recommends one more dose of OPV at 4 to 6 years of age along with 2nd booster dose of DPT. Govt. of India under EPI does not recommend any more dose of OPV and 2nd booster dose of DPT at 5 years and recommends only DT as 2nd booster at 4 to 6 years of age.

Initially EPI recommended only 3 primary doses in first year of life and one more dose of OPV at 18 to 24 months. The seroconversion and protection with only 3 primary doses was shown to be as less as 60 percent in some studies. This was also proved by the fact that poliomyelitis did occur even in a fully immunized child. Hence, Indian Academy of pediatrics and most of the pediatricians recommend 5 primary doses in first year of life to have better efficacy (80-90% protection) and lesser chances of mishap. Now the EPI recommends an extra OPV during primary schedule as zero dose at birth. As the immunity can wear off and lead to risk of polio by 5 years IAP also recommends one more dose at 4 to 6 years of age.

Efficacy/Seroconversion

The efficacy of 3 doses of OPV in West is around 80 to 90 percent while that in temperate countries like India is only 60 to 70 percent.

The reasons behind poor efficacy in temperate climate are multifocal:

- Poor cold chain maintenance
- Interference by other GI viral infections
- Genetic reasons

The efficacy goes up to 90 percent with 5 doses of OPV in India. Theoretically, one may require 10 to 15 doses of OPV to reach near 100 percent efficacy. This is achieved by pulsing for 3 to 5 years with 2 pulse polio doses every year as has been proved in some countries.

With IPV, sero conversion rates are 90 to 95 percent after 2 doses and 99 percent after 3 doses. It produces excellent humoral immunity as well as local pharyngeal and, possible intestinal immunity.

These antibodies persist for several years after primary immunization with IPV. Study in Tamil Nadu (India)

comparing efficacy of OPV and IPV has shown higher efficacy with latter (66% vs 92%). There were initial concerns that IPV induces lower level of mucosal immunity than OPV and it doesn't get excreted in the stools of vaccines so it may be less efficacious in preventing wild virus circulation. But now studies have shown that enhanced IPV (eIPV) induces adequate amount of IgA formation in nasopharyngeal and intestinal secretions almost equivalent to that induced by oral polio vaccine.

Mechanism of Action

When OPV is given by mouth, the vaccine viruses reach the intensities where they must establish infection (vaccine virus 'take') before an immune response may occur. A high level of gut immunity ensures that vaccinated children would not participate in the chain of transmission of wild (pathogenic) polioviruses.

Poliovirus has been widely studied for many decades, and many significant scientific discoveries have been made during this time. However, research on specific mucosal and cellular immune responses has not been performed until very recently in the history of polio vaccines. The cellular immunity necessary for poliovirus clearance and its role in the development of the disease poliomyelitis are still not well defined. The immunological background of individuals predisposed to contract poliomyelitis is still undefined and further investigations are required to gain a comprehensive picture of the host immune status and susceptibility to polio disease.

Mucosal Responses

Mucosal immunity is the first line of defense for protection against poliovirus infection. IgA was found to be the predominant immunoglobulin class in external secretions and exhibited structural differences compared to IgA found in serum. On mucosal surfaces, IgA exists mainly as a dimeric molecule that possesses a unique secretory component (s.c.) secretory IgA also contains one J chain per four light chains. The structure of S-IgA is thought to help the molecule survive in the harsh environment of low pH and proteases of the intestinal mucosa. The majority of S-IgA is synthesized locally in plasma cells found predominantly beneath the epithelium of secretory surfaces. Another component of S-IgA, the s.c., is found primarily in the mucosal epithelium. The dimer of S-IgA is produced in the plasma cells below the site where s.c. is made. As dimeric IgA passes through the epithelium, it combines with the s.c. portion. The joining of the two molecules completes the S-IgA molecule. Many studies have been performed to establish the concept of a common mucosal immune system where IgA precursor cells emigrate to different mucosal sites such as mesenteric lymph nodes, lamina propria of the small intestine and bronchi, gestational mammary glands, salivary glands, genital

areas, and ocular area to provide protection at these portals of entry into the body.

Salk IPV induces the production of IgM, IgG and IgA antibodies in serum. IPV Salk, however, was found not to induce a significant neutralizing secretory antibody (S-IgA) response in the alimentary tract or nasopharynx. IPV may not induce a good secretory immune response due to the limited amount of antigen that presents itself to the gut associated lymphoid tissue (GALT). A booster effect has been seen in individuals previously primed with IPV Salk upon revaccination with IPV Salk as well as a modest secretory antibody response. Oral poliovirus vaccine induces secretory immune and neutralizing antibody responses in the mucosal sites that are superior to those elicited by IPV. Mucosal immunization (intranasal) with IPV induces a secretory antibody response that is superior to immunization by the parental route. Parenteral administration of IPV – Salk induces much less mucosal immune response, although eIPV has been found to induce more of a mucosal response compared to IPV Salk. Boosting with OPV after immunization with IPV leads to an enhanced S-IgA response. Table 1 summarizes the features of the immune responses induced by conventional inactivated and live vaccines administered by parenteral and mucosal routes, and correlates to responses to vaccination with Salk and OPV, respectively.

Immune responses have been measured in children receiving IX enhanced potency IPV, double strength eIPV, or quadruple strength eIPV and compared to OPV immune responses. Responses to types 1 and 3 poliovirus in eIPV vaccines were compared to those of infants receiving three

doses of OPV at 6, 12 and 18 weeks of age. Secretory IgA responses measured in salivary samples were greater in OPV vaccines compared to any of the IPV groups. Secretory IgA appears to have a role in inhibiting the application of poliovirus at mucosal surfaces. This is exemplified by a study where IgA deficient individuals were found to shed poliovirus for prolonged periods of time after oral vaccination. Even though an enhanced potency formulation of IPV induced better secretory responses compared to earlier IPV formulations, the responses still do not meet or exceed the response elicited by OPV. These data are important for illustrating the difference in immune response elicited by a live-replicating vaccine virus versus a parenterally administered vaccine. To gain the benefit of both vaccines, combination schedules have been investigated. Combination of IPV immunization first with OPV to follow may help prevent vaccine associated disease while still inducing superior local immunity found with OPV vaccination.

T-Cell Responses

Firstly evidence that T-cell responses were important for polio clearance came from individuals with severe T- cell deficiency, these individuals became chronically infected with poliovirus; one individual described in these studies came down with paralytic poliomyelitis.

Polio specific cellular immune responses have recently been studied. The aim of these studies was to begin to understand the participation of cell mediated immune responses in clearance of virus and in the

Table 1: Features of immune responses

<i>Features of response</i>	<i>Response to immunization by indicate route and type of vaccine</i>	
	<i>Parenteral inactivated</i>	<i>Mucosal live</i>
Immunologic response similar to natural infection	–	+

Persistence of secretory immune response	–	+
Development of secretory immunity in other mucosal sites and milk	–	+
Protection against mucosal natural reinfection	–	+
Protection against systemic disease after natural reinfection	+	+
Development of herd immunity via spread of vaccine virus to contacts	–	+

potential destruction of nervous tissue infected with poliovirus. First step in answering these questions have been to define T- and B cell epitopes on the poliovirus cased. The mouse model has been used to study T-cell responses to polio. T helper and CTL epitopes have been localized in capsid protein VP1 in areas of the protein that were identified as neutralizing antibody recognition sites. Both virus and VP1 capsid protein induced a major histocompatibility complex class I restricted T-lymphocyte response. Vaccine recombinants expressing different portions of the polio capsid proteins VP1, VP2, VP3 and VP4 were used to define regions of the capsid proteins recognized by bulk virus specific CTL population. The CTL population was found to recognize target cells carrying VP1 sequences but not sequences of VP2, VP3 or VP4. In contrast, peripheral blood mononuclear cells of Sabin immunized human donors proliferated to all four capsid proteins. This indicated the presence of T-cell epitopes located in all four capsid proteins. The contribution of CTL response to virus clearance or damage of nervous tissue remains unknown but the studies described have provided a basis to investigate these questions.

Nature of immunologic reactivity after parental or mucosal immunization with Conventional Live or Inactivated Vaccine.

Advantages and Disadvantages

OPV is cheaper and being given orally is more acceptable. It is safe with virtually no side effects. It includes both local gut as well as systems immunity. It leads to excellent herd immunity. Mass vaccination is easier with oral vaccine. IPV is available in injection form and is costlier. It can precipitate paralytic polio in a child who is in incubation

period of wild polio especially during epidemics. Hence OPV is preferred over IPV for routine and mass vaccination (Table 2).

But on the other hand, OPV is less efficacious in tropical climate. It has the potential of vaccine-associated paralysis (VAP) and worldwide experience has proved that polio eradication is not possible just by high coverage of universal immunization with OPV. It also needs strict cold chain maintenance. Whereas IPV is more efficacious, less thermolabile and has no chances of vaccine induced paralysis. Of late even IPV is shown to lead to local gut immunity as well as herd immunity. Good routine coverage of 5 primary doses of IPV can eradicate polio from a country. However, pulsing is easier with OPV than with IPV.

The second major problem with use of OPV is the emergence of circulating Vaccine Derived Polio Viruses (cVDPVs), which are mutants that re-acquire wild virus-like properties and have been in communities with low population immunity especially when polio vaccine coverage rates decline but OPV use continues. The duration and extent of spread of cVDPVs are dependent on the magnitude of the immunity gap. As long as OPV is in use it is mandatory that very high immunization coverage must be maintained so as to decrease the risk of emergence of cVDPV. Whereas VAPP occurs in individual cases, cVDPV can result in large outbreaks.

It has been suggested that mass OPV campaigns should be synchronized with the cessation of OPV use once eradication of wild poliovirus has been achieved, so as to eliminate the risk of VAPP and the emergence of cVDPVs. At the same time, a gradual transition to IPV should be encouraged.

Table 2: Comparison of OPV vs IPV

	<i>OPV</i>	<i>IPV</i>
Type	Live	Killed
Route	Oral	IM
Cost	Cheap	Costly
Storage	2-8° can be frozen	2-8°C (Strictly)
Doses (primary)	5	3
Side effects	Mild	Mild
Vaccine induced paralysis	+	-
(VAP) Injection induced PPT of paralysis	-	+
Efficacy	++	+++
Pulsing	Possible	Difficult
Gut immunity	++	-
Herd immunity	++	-
Use in immune compromised host	No	Yes
Interference with virus isolation	+	-

There are few limitations of IPV as well:

- Virus content is 10,000 times more than OPV hence it is costlier.
- Requires trained personnel to administer.
- No excretion of virus, hence contacts are not benefited.
- Not useful in controlling epidemics.
- Injection is to be avoided in epidemic times, as there is risk to paralysis.
- Lack of feasibility for mass administration.

Herd Immunity

The protection extended to even the unvaccinated by mass vaccination is called as herd immunity. For a disease to occur one needs the infecting organism, the susceptible host and the cycle of transmission. In an endemic area, the cycle of transmission continues from one infected person to another susceptible and so on. Herd immunity in polio is possible in two ways. One is the excretion of vaccine poliovirus, which can infect the unvaccinated susceptible contacts and leads to indirect vaccination. However, as the vaccine virus is an attenuated strain, this may not be very efficacious. The second way of herd immunity is blocking the transmission of poliovirus. When many hosts are vaccinated, especially simultaneously the transmission of wild virus is blocked, as it cannot find a suitable susceptible host. The virus cannot survive in environment for more than 48 to 72 hours. This appears to be a major way of herd immunity and the mechanisms behind the pulse strategy. When 80 to 90 percent of susceptible hosts are vaccinated, the herd effect will protect remaining 10 to 15 percent unvaccinated hosts.

Side Effects

OPV has minimum side effects. It can lead to GI upset like diarrhea, vomiting. It does not lead to fever. The most important but extremely rare side effect with OPV is vaccine-associated paralysis (VAP). It occurs in 1 in million doses. Massive benefits of OPV far outweigh the rare risk of paralysis. In west, though, it can become a medico-legal problem. Hence in west, people use first IPV to induce systemic antibodies and then use OPV, which will lead to local gut immunity without the risk of vaccine induced paralysis due to the partial immunity conferred by prior IPV.

IPV can lead to local side effects like pain, swelling, redness and tiredness in 10 to 20 percent of vaccines. It can lead to fever, which is mild and lasts for 24 to 48 hours. If not given at proper site it can damage important nerves like sciatic nerves if given in gluteal region. Like any other IM injection it can precipitate paralysis in a patient who is already in incubation period of polio, as can occur during polio epidemics. Hence, IPV or any other IM injection should be avoided in an unimmunized sick child with fever especially during seasons of polio epidemics. Lastly, like any other injection, an abscess may form if aseptic precautions are not followed while giving IM injection.

Polio Eradication

Defined as no case of paralytic poliomyelitis by wild poliovirus in last three calendar years along with absence of wild poliovirus in the community, when excellent clinical and virological surveillance exists and the coverage of routine OPV is more than 80 percent. Polio elimination is defined as no case of paralytic poliomyelitis by the wild poliovirus in one calendar year with other criteria being the same as in eradication. Adequate immunization, clinical surveillance and appropriate virological investigations in all children with acute flaccid paralysis (AFP) are the cornerstones of polio eradication.

Pulse Polio Immunization

It is a strategy of mass immunization by which one can eradicate poliomyelitis. Extra doses (pulses) of OPV are given to all children below 5 years of age in an area (like country, state, city) at a time on a given day (or few days). Such pulses are repeated every year. The aim is to achieve 100 percent coverage.

Who Should be Given Pulse Polio Doses?

The aim is to flood the intestines of susceptible hosts by OPV. Hence, all children <5 years of age should receive pulse OPV and this is given even if they have completed their routine OPV, even if they have taken a vaccine in recent past, they are going to receive a vaccine in the recent future, even if they are hospitalized, even if they may have taken or not taken prior pulse doses of OPV. Only very sick children especially in hospital intensive care units, preterm babies, leukemia children or severely immunocompromised children should not be given pulse OPV. Even those who are traveling should receive the pulse dose wherever they are on the day of pulse immunization. Even if a baby is born after the last date of registration or even if the name is not found at a center, pulse OPV must be given at any nearby center.

How does Pulse Immunization Work?

Wild poliovirus can survive either in the intestines of a susceptible host (usually children <5 years of age) or in the sewage water. In the sewage water it can survive only for 48 to 72 hr. And, hence, it has to find shelter into another susceptible host for it to survive and to continue cycle of transmission. When pulse OPV is given to all the children of <5 years of age, the intestines of these children are flooded by vaccine virus and hence wild poliovirus cannot get entry into it. As wild poliovirus cannot survive for more than 48 to 72 hr in environment, its circulation will drastically fall when such pulse is repeated after 6 weeks it still further reduces transmission. Such pulses done every year will ultimately eradicate the wild poliovirus from nature.

How Many Pulses are usually Required?

Strategy of 2-pulses/year as NID and 2 to 4 SNIDs per year takes about 5 years or so of such pulsing in developing countries to eradicate polio. Unfortunately multiple problems of administration and complacency at all levels have delayed eradication in India. Year 2011 has brought some cheer and hope among all the workers who are toiling hard since last 15 years. We may achieve '0' polio status by mid 2012.

Precautions and Contraindications

People who have had severe allergic (anaphylactic) reactions after a previous dose of IPV, or to streptomycin, polymyxin B, or neomycin should not be administered IPV. They should receive OPV. There have been no adverse effects in women who have received IPV during pregnancy; however, in theory it should be avoided. If a pregnant woman is at an increased risk for infection and requires immediate protection, IPV should be administered in accordance with the recommended schedules for adults.

For persons with a disorder or condition that make it hard for the body to fight infection or are immune deficient, the IPV is the only type of vaccine recommended. This includes persons with AIDS, HIV infection, and other immunodeficiency diseases (cancer, leukemia, lymphoma, and so on). It also includes people who are receiving radiation treatments, medications to treat cancer, corticosteroids (such as prednisone), or other immunosuppressive medications.

IPV can be given during breastfeeding and to a child who has diarrhea. Persons who have minor upper respiratory illnesses with or without fever, mild to moderate local reactions to a previous dose of vaccine, current antimicrobial therapy or are in the improvement stage of an acute illness may all still receive the vaccine. Those who are moderately or severely ill should usually wait until they have recovered before receiving the vaccine.

HIV in Children: Clinical Features and Diagnosis

Triptei Pensi

BACKGROUND

HIV is a preventable infection. The incidence of new HIV infections has leveled off but is not in rapid decline. Approximately 90 percent of all HIV positive people in the world live in developing countries. Many societal factors are driving the spread of the epidemic, including people on the move, complex emergencies, cultural factors, (e.g. the status of women), poverty, stigma, and denial. HIV is most commonly transmitted during high-risk events such as unprotected sex with an infected person; blood-to-blood contact with an infected person; and pregnancy, childbirth, and breastfeeding by HIV positive women.

Globally, the number of children younger than 15 years living with HIV has increased from 1.6 million in 2001 to 2.5 million in 2009. However, the number of newly infected children has been declining since 2003 due to increasing access to prevention of parent-to-child transmission (PPTCT) services. In 2009 alone, globally, 370,000 children under the age of 15 years were newly infected, i.e. around 1,000 a day; and 260,000 died, the majority under the age of five.¹

In India, with 27 million pregnancies annually, and an estimated overall HIV prevalence of 0.48 percent in antenatal women, it is estimated that there are 1,29,600 HIV-infected pregnant women annually.² If no intervention is done, this would mean adding 38,880 infants with HIV infection, using a conservative vertical transmission rate of 30 percent, however, with the present national PPTCT program, this figure should be estimated at approximately 19,440 infants with HIV infection through vertical transmission. HIV disease progresses very rapidly in young children, especially in the first few months of life, often leading to death. HIV infected infants frequently present with clinical symptoms in the first year of life. Without care and treatment, about one third of infants living with HIV will die in their first year of life and almost 50 percent of children by the second year of life.

ROLE OF HIV EPIDEMIOLOGY IN HIV DIAGNOSIS

HIV Types 1 and 2

There are two primary types of HIV that cause AIDS—HIV type 1 (HIV-1) and HIV-2 (Fig. 1). HIV-2 is limited largely to western Africa, whereas the more contagious HIV-1 continues to drive the current pandemic. For this reason, most diagnostic laboratory tests focus on HIV-1; however, most standard ELISA technology will detect antibodies to both HIV-1 and -2. The particular tests needed to identify HIV-2 are sometimes different from those used for HIV-1, and providers must exercise caution when using HIV-1 lab tests in areas with higher rates of HIV-2 infection.

The subtypes of HIV-1 also differ by continent and region. Although most new infections are subtype C, the geographic distribution of HIV-1 subtypes is complex. Africa, for example, has most subtypes but little subtype B, whereas the United States has a higher prevalence of subtype B. Type C is prevalent in India in majority of the region. HIV diagnostic tests detect specific proteins and/or genetic material (i.e. HIV DNA and RNA PCR), and many are designed and engineered for the subtype(s) of HIV in a particular population. Health care workers must be familiar with the distribution of certain subtypes in their region and to understand the potential limitations of diagnostic tests depending on local prevalence

DIAGNOSIS OF HIV INFECTION

Several types of HIV diagnostic tests have been developed. The affordability and availability of these tests vary by country. Diagnostic tests fall into two main categories; antibody tests (HIV rapid tests, HIV enzyme-linked immunosorbent assay [ELISA; also called EIA {enzyme immunoassay}], and Western blot) and virologic tests (HIV DNA polymerase chain reaction [PCR] assays, RNA assays, p24 antigen assays, and viral culture).

Fig. 1: HIV structure

- Subtype A:** Central Africa sub-Saharan Africa
- Subtype B:** South America, Brazil, United states, Thailand, Europe, Caribbean, India, Japan
- Subtype C:** Brazil, India, South Africa
- Subtype D:** Central Africa, sub-Saharan Africa
- Subtype E:** Thailand, Central African Republic, Southeast Asia
- Subtype F:** Brazil, romania, democratic republic of congo (zaire)

Type of tests	
Antibody	Virologic
HIV rapid test	HIV-1 DNA PCR
HIV ELISA (also called EIA)	HIV-1 RNA PCR (viral load)
Western blot	Ultrasensitive <i>p24</i> antigen assay test
	HIV culture

COMMON DIAGNOSTIC TEST

Once HIV infection is diagnosed, the stage of infection can be established clinically and immunologically. Staging the severity of the patient’s disease allows health care professionals to determine the best time to initiate treatment with antiretroviral (ARV) therapy.

Antibody Tests

One type of laboratory test used to diagnose HIV is the antibody test. This category of test includes HIV rapid tests, ELISA, and western blot. Antibody tests, as the name suggests, detect the antibodies that are produced during the immune response to HIV.

Because antibody tests are inexpensive and relatively easy to perform, they are the most widely available. Antibody tests have both advantages and disadvantages. Like most lab tests, they can yield false-negative and false-positive results.

False-negative tests occur when HIV-infected individuals do not produce detectable antibodies, such as during the early, acute phase of the infection (“window” period) and the very late stages of infection (when immune suppression is severe and antibodies are no longer being produced in response to HIV infection). Usually, individuals produce antibodies within 6 weeks of infection, and almost all infected individuals have detectable antibodies by 12 weeks postinfection. However, some may take as long as 6 months to make detectible antibodies. For this reason, the World Health Organization (WHO) and NACO^{3,2}

recommends using the antibody test 6 weeks after exposure to HIV because almost all infected individuals will have detectable antibodies (also called seroconversion) by then.

Regardless of exposure history, a negative antibody test should be interpreted with the window period in mind. Also, a negative test does not exclude HIV in an individual with continual or recent exposure to HIV (e.g. breastfeeding infants or persons engaging in high-risk behavior).

The other primary cause of false-negative antibody tests is severe immunosuppression. During the very late stages of HIV-infection, antibody levels can fall so far as to become undetectable. When a false-negative is suspected in the presence of severe clinical symptoms, further testing is required.

One of the most important diagnostic limitations of antibody tests occurs in infants younger than 18 months. During pregnancy, HIV-infected mothers passively transfer immunoglobulin G HIV antibody to the infant through the placenta. The presence of these antibodies means that the infant is exposed and might be infected.

Rapid Test (Fig. 2)

The development of HIV rapid tests in the 1990’s increased access to testing and care, especially in resource-limited settings. These simple antibody tests can be performed at the point of care and have a fast turnaround time, with results available within 15-30 min. These tests are inexpensive (US\$1-\$2 per test) and are ideal for situations in which an immediate result is necessary (e.g. a pregnant woman in labor). Also, they can be done with a simple heel, toe, or finger prick. Rapid tests are highly sensitive (99.3-100%) and specific (98.6-100%). (A sensitivity of 99.3 percent means that the test is falsely negative only 0.7 percent of the time, and a specificity of 98.6 percent means that the rapid test is falsely positive only 1.4 percent of the time.). Like all diagnostic tests, rapid tests need to be interpreted within the context of the clinical situation. The window period needs to be considered any

Fig. 2: Rapid slide test

time that there is a negative rapid test, and positive rapid tests need to be interpreted with care in infants.

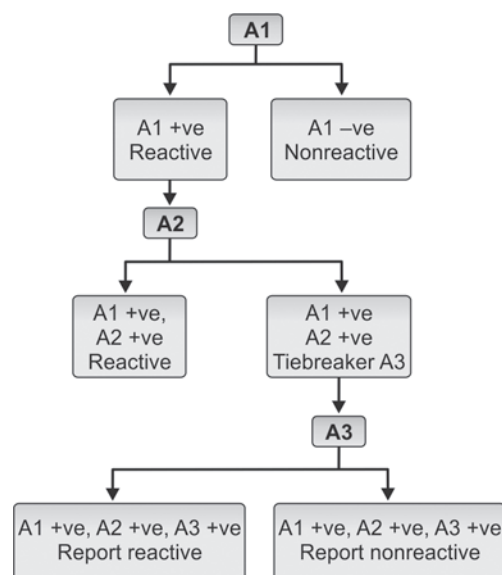

Rapid Antibody Test

ELISA: Like the rapid test, ELISAs (also called EIAs) are inexpensive and highly sensitive in identifying antibodies to HIV (meaning rarely falsely negative). Though several conditions can cause an ELISA to be falsely positive—autoimmune disease, certain viral infections, syphilis, hematologic malignancies, pregnancy, and recent blood transfusions—the test is also specific (rarely falsely positive). Compared to the HIV rapid test, however, ELISA has several disadvantages, including the need to perform a venous blood draw (rather than a simple skin prick), the need for laboratory facilities, and the longer turnaround time for results.

Because of the low levels of antibodies during the window period, the first generation of ELISAs were frequently falsely negative for a long time after initial infection. Fourth generation have been developed to capture existing antibodies at lower levels. With each successive generation of ELISA's, the window period has decreased significantly and the test has become more useful.

ELISAs usually require serum samples for processing, but tests that use urine or oral fluid have also been developed. ELISA is usually a qualitative (i.e., positive-negative type) test, but semiquantitative ELISAs have also been developed. These tests can estimate the amount of antibody present and detect trends in the quantity of antibody over time. Although these tests are potentially useful in monitoring the decrease in an infant's maternal antibodies during late infancy, they are less useful in the

Flow chart 1: HIV testing strategy IIB (blood/plasma/serum)
Adapted from NACO (2007) antiretroviral therapy guidelines

first months of life and are not included in most current guidelines.

A negative ELISA does not require confirmatory testing, provided that the patient was not tested during the window period. A positive ELISA, however, should be confirmed with a Western blot assay to further minimize the possibility of a false result (Flow chart 1).

But Western Blot is rarely used nowadays, except for research purpose.

National testing guidelines for children above five years:

The guidelines are same as adults that for symptomatic person the sample should be reactive with two different kits (Flow chart 1). For asymptomatic case the sample should be positive with three different kits (Flow chart 2) i.e., with different principals. The blood sample collected is tested with first kit, if it is reactive then it is retested sequentially with second and third kits.²

Western Blot

Western blot is another category of antibody test that detects the presence of antibodies against specific HIV proteins. Western blots are typically used to confirm a reactive ELISA result. The Western blot test is a polyacrylamide gel electrophoresis that detects several proteins that are specific to HIV antibodies (*p24*, *gp41*, *gp120*, *gp160*). If these proteins are not seen, the Western blot is negative. If most or all of the proteins are seen, the Western blot is positive. A negative Western blot indicates that the positive ELISA or rapid test was a false-positive. A positive Western blot confirms the presence of HIV-1 antibodies. An indeterminate Western blot could mean early infection or, in an uninfected, exposed infant, the partial loss

However, p24 lab equipment is not yet commercially available on a scale that would allow national coverage, and the recent decrease in the price of other virologic tests (e.g. DNA and RNA PCR) has decreased p24's price advantage.

HIV Culture

HIV culture is a virologic test that requires incubating peripheral blood cells from a patient to determine the presence of HIV in the blood sample. The sensitivity of HIV culture is the same as that of DNA PCR. However, HIV culture is expensive and time consuming, taking up to 6 weeks to obtain results, it is therefore used for research only. HIV culture is also unavailable in most settings and is no longer the test of choice for diagnosis of HIV in infants, children, or adults.

DBS AND HIV TESTING

Until recently, HIV testing required a phlebotomist, a centrifuge, and quick transport of the serum sample between the health clinic and the lab. The development of the DBS collection method has eliminated many of these logistical barriers and has provided increased access to HIV testing.

DBS simplifies blood sample collection and, owing to its high stability, allows for convenient sample handling and transport. Only a few drops of blood are required from a finger, toe, or heel stick, which are collected on special filter paper. The DBS cards are then dried; specially packaged; stored in a plastic, zip-locked bag; and transported to the lab at room temperature. See the "How to collect DBS" text box for more information on this collection technique (Fig. 3).

DBS collection has been used successfully to perform virologic and antibody tests, including DNA PCR, RNA PCR, p24 antigen detection, and ELISA. Both DNA and RNA DBS samples are stable for more than a year when properly collected and stored. DNA PCR using DBS technology is as accurate as DNA PCR testing on whole blood (sensitivity of 100% and specificity of 99.6%). Testing programs using DBS are currently being implemented in various countries, and they have greatly facilitated the early infant diagnosis of HIV.

Antibody Testing in Infants

Early diagnosis and treatment of HIV can greatly affect child survival. The high mortality rates of infected infants underscore the importance of early diagnosis. Without interventions, up to 30 percent of infants born to HIV-positive mothers are infected during pregnancy, delivery, and breast-feeding. Median infant survival time after HIV infection in infancy is just over a year. Without treatment, one in five HIV-infected infants dies before 6 months, more than a third die by 1 year, and more than half die before 2 years.

Diagnostic testing for HIV-1 in infants younger than 18 months differs from that for older children, adolescents, and adults because of the presence of maternal antibodies. HIV-specific immunoglobulins such as immunoglobulin G HIV antibodies are passively transferred to the infant across the placenta. The mean age for clearing maternal antibody is just over 10 months, but maternal antibodies may persist in the infant until 18 months of age.

Because antibodies are transferred to the fetus during pregnancy, antibody tests such as rapid tests and ELISA are positive in all newborns of HIV-infected mothers, including infants who are not infected. Even if an infant becomes infected and begins making his or her own antibodies, antibody tests cannot differentiate between antibodies from the mother and those from the infant. Therefore, a positive antibody test in infancy indicates that an infant has been exposed and may or may not be infected.

Despite these factors, HIV antibody testing is still a useful screening tool later in infancy. Up to 93 percent of 9-month-old HIV-uninfected infants and 95 percent of 12-month-old HIV-uninfected infants will have lost their maternal antibodies. For this reason, a positive test later in infancy is more likely to indicate HIV infection. Many national guidelines recommend first doing a rapid test in infants aged 9 months to see if they are still antibody positive and then doing the more expensive virologic testing on those that still have circulating antibodies. This approach provides health care providers with a simple and relatively inexpensive strategy to exclude HIV infection in many infants aged 9 months because uninfected infants are likely to be antibody negative at that time.

Virologic Testing in Infants

During early infancy, when maternal HIV antibodies can complicate the interpretation of antibody tests, virologic tests can be used to determine whether the infant is HIV infected. Virologic testing is becoming increasingly available worldwide and has an increasing role in guiding early clinical decisions related to feeding choices, cotrimoxazole prophylaxis, and early HIV care and treatment.

In countries in which pediatric ARV therapy and infant formula are readily available and resources permit multiple tests, infants of HIV positive mothers are tested at 14 to 21 days, 1 to 2 months, and 4-6 months. Some experts also recommend testing at birth to capture those infected during pregnancy. However, this approach is not practical in resource-limited settings, where often only one virologic test is available per child.

In these settings, the DNA PCR test is often performed at 6 weeks of age or at the earliest clinical encounter thereafter. Testing at 6 weeks allows the provider to detect prenatal and perinatal infections and ensures that exposed infants begin to integrate into the child health care system (e.g. for immunizations and cotrimoxazole prophylaxis).

1. Fill out appropriate paperwork: DBS card lab order form, clinic logbook.

2. Choose the puncture site

Small infants (<4 mos, <5 kg)

- Puncture the **heel**
- Not finger, since risk of hitting bone

Medium infants (4-10 mos, 5-10 kg)

- Puncture the **toe**
- If malnourished, still use heel

Larger infants (>10 mos, >10 kg)

- Puncture 4th finger
- Slightly lateral side

3. Warm the puncture site

4. Wash hands, put on gloves

5. Position baby with foot down

6. Clean the site with an alcohol swab and allow to dry for 30 seconds

7. Press lancet on to site, prick skin

8. Wipe away first drop

9. Allow large drop to collect

10. Touch blood drop to card

11. Fill entire circle with drop

12. Fill all 5 circles (at least 3)

13. Apply mild pressure and clean the puncture site

14. Dry and package the DBS samples for storage and transport to the laboratory

Job well done!

Fig. 3: Method of collection of DBS sample (Photos courtesy of Julian Kim, MD: Baylor Initiative for Paediatric AIDS 2010)⁴
(For color version see plate 5)

In our National program NACO facilitates a second testing for reactive infants again at 6 months of age. However the gold standard for HIV infection conformation still remains antibody testing at 18 months. When HIV DNA

is used for diagnosis, the use of HIV drugs for PPTCT in mother or infant does not affect the test results.

If resources permit, a second DNA PCR test can be done 6 weeks after breastfeeding has stopped. Because

HIV exposure ends when a child is weaned from breast milk, this second DNA PCR allows for a definitive diagnosis in these children. DNA PCR tests are useful in other clinical scenarios as well, such as when an exposed infant older than 9 months with an unknown HIV status has a positive rapid test. Most HIV negative infants are antibody negative by 9 months, and DNA PCR testing can offer a definitive diagnosis in this case. Finally, even if an infant has an initial DNA PCR test that is negative, the test should be repeated if the infant later develops signs and symptoms of HIV infection

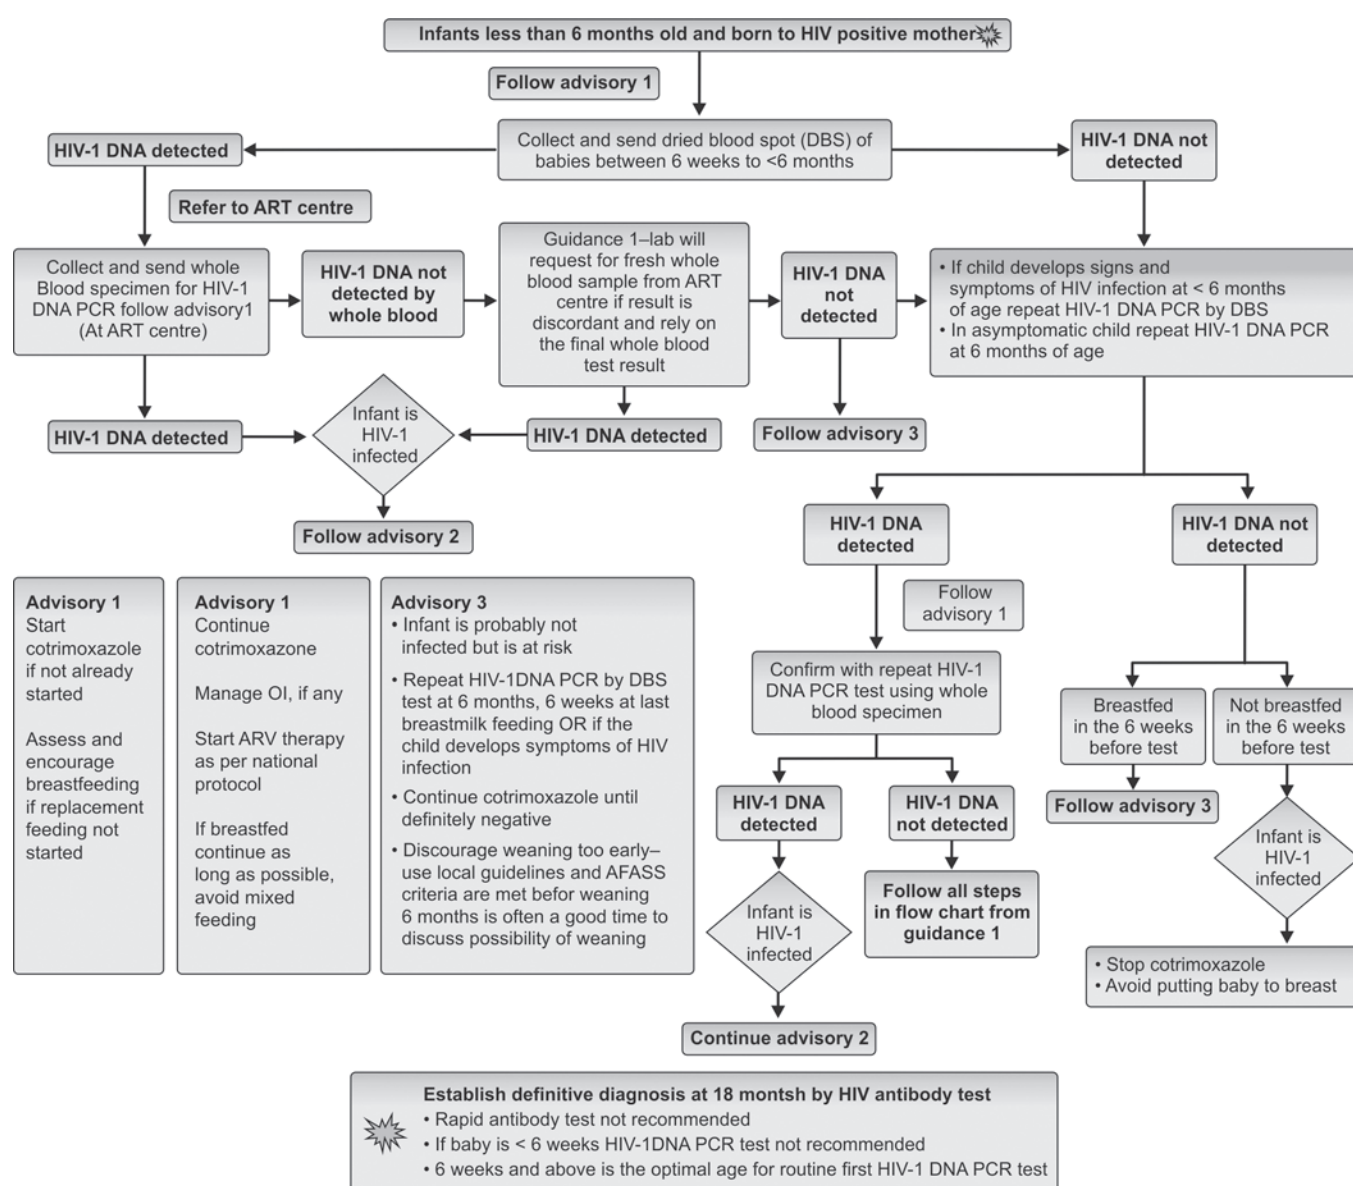

The Pediatric Technical Resource Group at NACO has provided testing algorithms for infants up to six months (Flow chart 3) and 6 to 18 months for confirmation of HIV infection in exposed infants (Flow chart 4).⁵

Additional algorithms used in other guidelines are given in annexure (I, II, III)

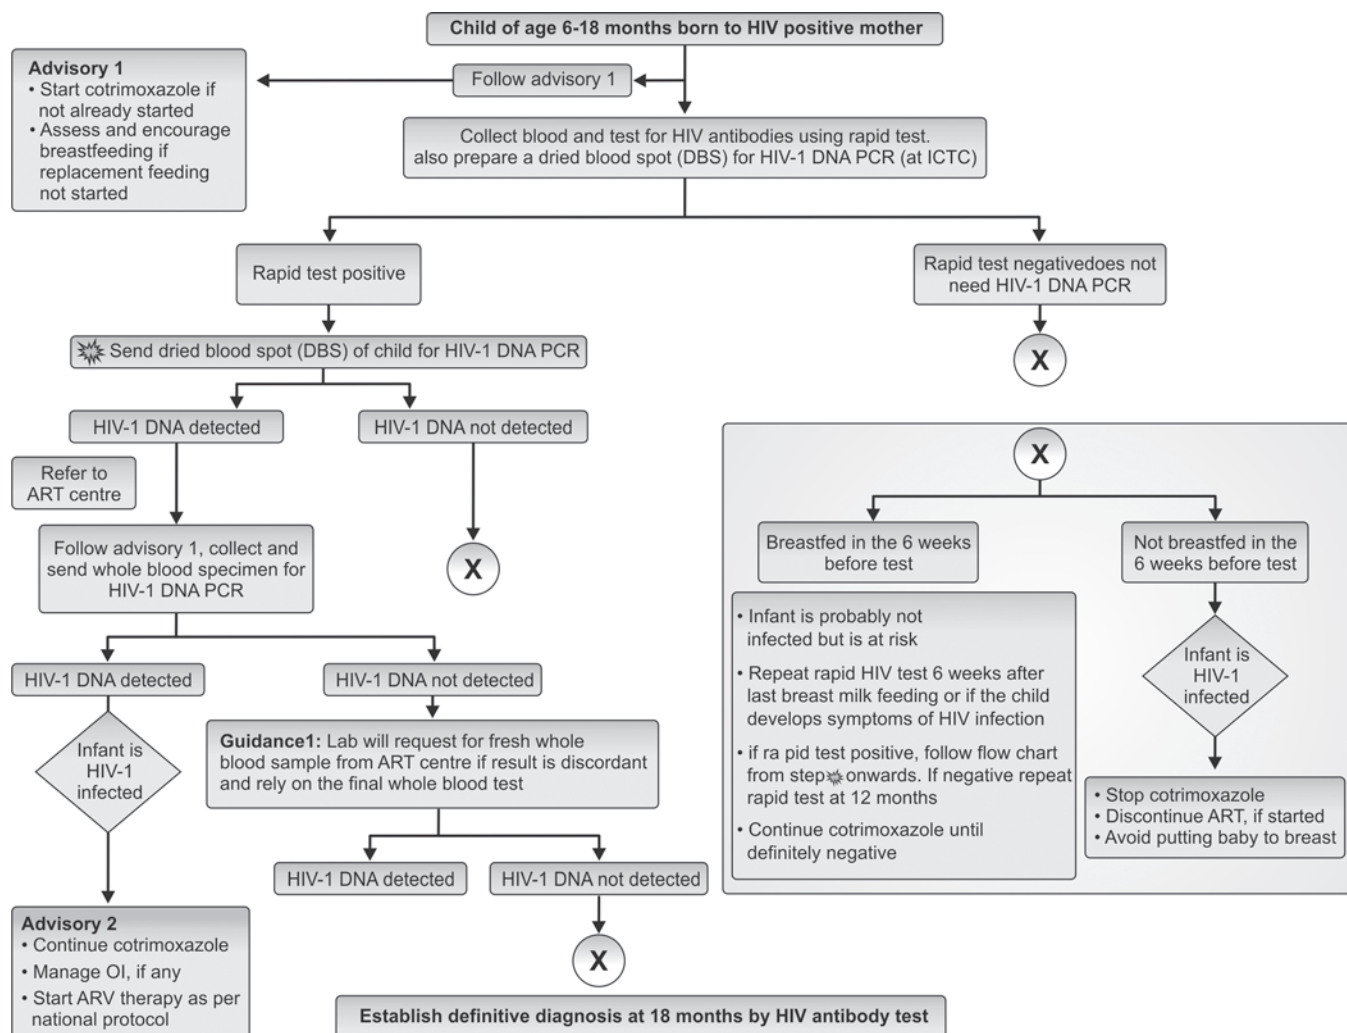

Presumptive diagnosis where there is no virologic testing available
If the child is less than eighteen months of age and has symptoms and signs that are suggestive of HIV infection and there is no virologic testing available, it is possible to make a presumptive diagnosis by addressing the following situation and by the help of the given table the child can be presumed positive the HAART is to be started in order to reduce the mortality in infants born to HIV positive mothers in resource limited settings (Flow chart 5).

- Does the child meet the clinical criteria for presumptive diagnosis of severe HIV infection?
- Is there evidence of HIV exposure—mother or baby's serology shows HIV antibody positive?

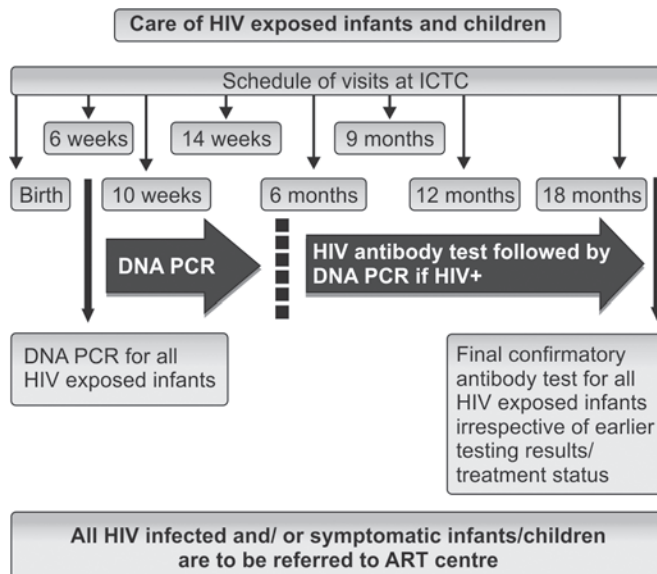

Flow chart 3: Management of a child <6 months born to an HIV positive mother

Flow chart 4: Management of a child 6-18 months born to a HIV positive mother

Flow chart 5: Care of a child born to a HIV positive mother

- Is there evidence of immune suppression (low CD4 count/%) and/or symptoms or illnesses consistent with HIV infection?

Clinical criteria for presumptive diagnosis of severe HIV disease in infants and children less than 18 months of age requiring ART in situations where virological testing is not available

A presumptive diagnosis of severe HIV disease should be made if:
The infant is confirmed HIV antibody positive; and
Diagnosis of any AIDS-indicator condition (s) can be made; or
The infant is symptomatic with two or more of the following:

- Oral thrush;
- Severe pneumonia;
- Severe sepsis.

Other factors that support the diagnosis of severe HIV disease in an HIV seropositive infant include:

Recent HIV-related maternal death; or advanced HIV disease in the mother;
CD4 <20%.

Confirmation of the diagnosis of HIV infection should be sought as soon as possible.

Notes: As per IMCI definition:

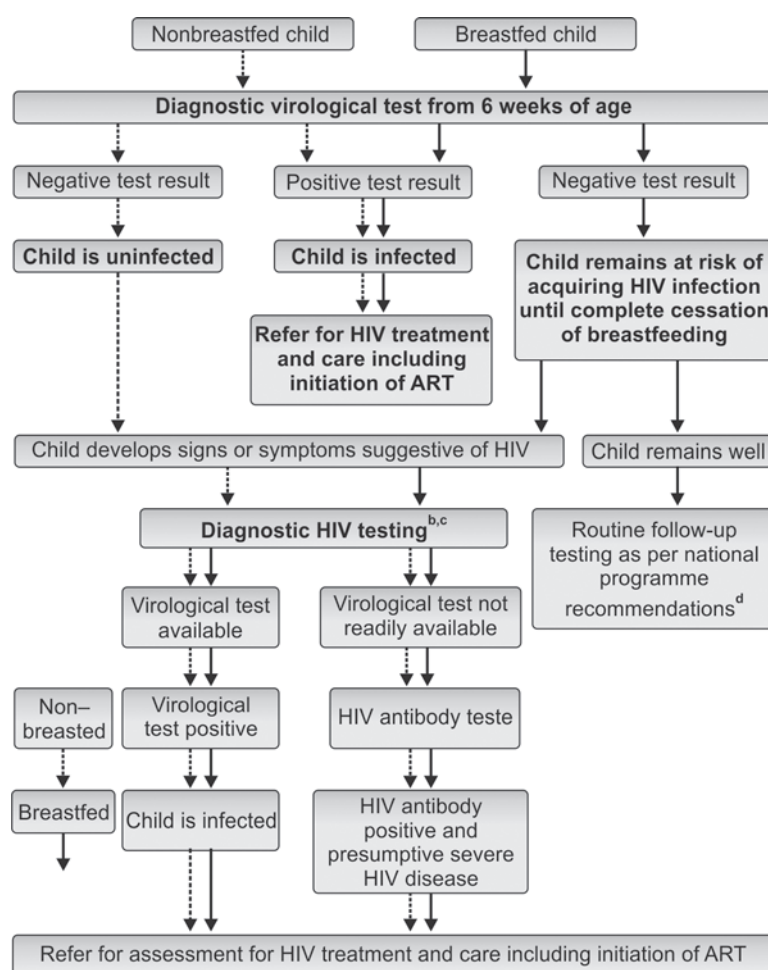

1. *Oral thrush*: Creamy white to yellow soft small plaques on red or normally colored mucosa which can often be scraped off (pseudo membranous), or red patches on tongue, palate or lining of mouth, usually painful or tender.
2. *Severe pneumonia*: Cough or difficult breathing in a child with chest indrawing, stridor or any of the IMCI general danger signs, i.e. lethargic or unconscious, not able to drink or breast-feed, vomiting, and presence or history of convulsions during current illness; responding to antibiotics.
3. *Severe sepsis*: Fever or low body temperature in a young infant with any severe sign such as fast breathing, chest indrawing, bulging fontanelle, lethargy, reduced movement, not feeding or sucking breast milk, convulsions, etc.

Virologic Testing and Infant Feeding (Flow chart 6)

Appropriate infant feeding is crucial to a child's well-being and survival. Infant feeding counseling in the context of HIV should aim to provide the best possible nutrition to optimize growth, development, and survival while also preventing HIV transmission as much as possible. Nutritional counseling needs to balance the risk of HIV transmission through breast milk with the risks of replacement feeding—improper infant replacement feeding itself can lead to severe malnutrition and death.

For each patient, one must assess the acceptability, feasibility, affordability, sustainability, and safety (AEASS) criteria of replacement feeding to ensure that it

Flow chart 6: Evaluation of breast and nonbreast fed child

- a. The risk of HIV transmission remains if breastfeeding continues beyond 18 months of age.
- b. Infants over 9 months of age can be tested initially with HIV antibody test, as those who are HIV AB negative are not usually HIV infected, although still at risk of acquiring infection if still breastfeeding.
- c. In children older than 18 months antibody testing is definitive.
- d. Usually HIV antibody testing from 9 to 18 months of age
- e. Where virological testing is not readily available HIV antibody testing should be performed, it may be necessary to make a presumptive clinical diagnosis of severe HIV disease in HIV seropositive children (see box 1) confirmation of diagnosis should be sought as soon as possible.

is appropriate. Replacement feeding is possible only with access to clean water, a steady income to purchase formula and other supplies, fuel for safe preparation, HIV disclosure in the household, safe storage, and an understanding of the importance of proper preparation and delivery of formula.

In settings where replacement feeding with formula does not fulfil AFASS criteria, the WHO recommends exclusive breastfeeding for the first 6 months of life unless AFASS criteria can be fulfilled before then. Because HIV-positive mothers in many resource-limited areas cannot fulfil AFASS criteria, they are counseled to exclusively breastfeed. In these cases, the infant's need for adequate nutrition requires continued HIV exposure.

Clinical Staging of HIV Infection

Children infected with HIV often have severe disease when first evaluated, or they may develop AIDS over time, much like adults. Immunologic and clinical categories are used to evaluate the HIV disease status in children and to make treatment decisions.

Primary Infection or Acute Retroviral Syndrome

Primary infection refers to the time when HIV first enters the body. At the time of primary infection with HIV, a person's blood carries a high viral load, meaning that there are many individual viruses in the blood. The number of copies of virus per milliliter of plasma or blood can exceed 1 million. An acute retroviral syndrome is mainly encountered in adults and occasionally in older children and adolescents. Signs and symptoms of acute retroviral syndrome include fever, myalgia (muscle pain), headache, nausea, vomiting, diarrhea, night sweats, weight loss, and rash. These signs and symptoms usually occur 2–4 weeks after infection, subside after a few days, and often are misdiagnosed as influenza or infectious mononucleosis.

During primary infection, the CD4+ count in the blood decreases remarkably but rarely drops to less than 200 cells/ μ L. The virus targets CD4+ cells in the lymph nodes and the thymus during this time, making the HIV-infected person vulnerable to opportunistic infections and limiting the thymus's ability to produce T lymphocytes. HIV antibody testing using an enzyme-linked immunosorbent assay (ELISA) or enzyme immunoassay may yield positive or negative results depending on the time of seroconversion. DNA PCR and RNA PCR will be positive, but confirmation with Western blot analysis may yield an indeterminate result because seroconversion can take up to 2–8 weeks to occur. The average time to seroconversion is 25 days. This stage is not much appreciated in young children and in children who are infected by parents.

Clinical Latency/Asymptomatic Disease (Clinical Stage 1)

Although patients recently infected with HIV usually experience a “clinically latent” period of years between HIV infection and clinical signs and symptoms of AIDS, evidence of HIV replication and host immune system destruction exists from the onset of infection. Early during this time, referred to as Clinical Stage 1, the immune system produces antibodies in an attempt to protect itself from HIV. This is when the “viral set point” is established. The viral load of the set point can be used to predict how quickly disease progression will occur. People with higher viral load set points tend to exhibit more rapid disease progression than those with lower viral load set points.

During latency, HIV-infected patients may or may not have signs and symptoms of HIV infection though persistent lymphadenopathy is common. In HIV-infected adults, this phase may last 8–10 years and is very short 20–40 weeks in children less than 12 years. The HIV enzyme-linked immunosorbent assay and Western blot or immunofluorescence assay will be positive. The CD4+ count is greater than 500 cells/ μ L in children over 5 years of age.

Mild Signs and Symptoms of HIV (Clinical Stage 2)

HIV-infected people may appear to be healthy for years, and then minor signs and symptoms of HIV infection begin to appear. They may develop candidiasis, lymphadenopathy, molluscum contagiosum, persistent hepatosplenomegaly, papular pruritic eruptions, herpes zoster, and/or peripheral neuropathy. The viral load increases, and the CD4+ count falls to between 350–499/ μ L in children older than 5 years. Once patients are in this stage they remain in stage 2. They can be reassigned stage 3 or 4 if a condition from one of those occurs, but they cannot be reassigned to Clinical Stage 1 or 2 if they become asymptomatic.

Advanced Signs and Symptoms of HIV (Clinical Stage 3)

HIV-infected patients with weakened immune systems can develop life-threatening infections. The development of cryptosporidiosis, pulmonary and lymph node tuberculosis, wasting, persistent fever (longer than one month), persistent candidiasis, recurrent bacterial pneumonia, and other opportunistic infections is common. These patients may be wasting, or losing weight. Their viral load continues to increase, and the CD4+ count falls to less than 200–349 cells/ μ L in children older than 5 years.

Clinical Stage 4

Patients with advanced HIV disease, or AIDS, can continue to develop new opportunistic infections, such as

Pneumocystis jirovecii pneumonia (formerly *Pneumocystis carinii* pneumonia), cytomegalovirus infection, toxoplasmosis, *Mycobacterium avium* complex, cryptococcal meningitis, progressive multifocal leukoencephalopathy, Kaposi sarcoma and other infections that commonly occur with a severely depressed immune system. The viral load is very high, and the CD4+ count is less than 200 cells/ μ L in children older than 5 years. At this point in the disease course death can be imminent.

Who Clinical Classification

WHO Clinical Classification (Table 1)³

Table 1: WHO clinical classification

Clinical stage 1

Asymptomatic

Persistent generalized lymphadenopathy

Clinical stage 2⁽ⁱ⁾

Unexplained persistent herpatosplenomegaly

Papular pruritic eruptions

Fungal nail infections

Angular cheilitis

Lineal gingival erythema

Extensive molluscum contagiosum

Recurrent oral ulceration

Unexplained persistent parotid enlargement

Herpes zoster

Recurrent or chronic upper respiratory tract infections (otitis media, otorrhea, sinusitis, tonsillitis)

Clinical stage 3⁽ⁱ⁾

Unexplained moderate malnutrition or wasting not adequately responding to standard therapy

Unexplained persistent diarrhea (14 days or more)

Unexplained persistent fever (above 37.5°C, intermittent or constant, for longer than one month)

Persistent oral candidiasis (after first 6-8 weeks of life)

Oral hairy leukoplakia

Acute necrotizing ulcerative gingivitis or periodontitis

Lymph node tuberculosis

Pulmonary tuberculosis

Severe recurrent bacterial pneumonia

Symptomatic lymphoid interstitial pneumonitis

Chronic HIV-associated lung disease including bronchiectasis

Unexplained anemia (<8.0 g/dl), neutropenia ($< 0.5 \times 10^9/L^3$) and or chronic thrombocytopenia ($< 50 \times 10^9/L^3$)

Clinical stage 4^{(i) (ii)}

Unexplained severe wasting, stunting or severe malnutrition not responding to standard therapy

Pneumocystis pneumonia

Recurrent severe bacterial infections (e.g. empyema, pyomyositis, bone or joint infection, meningitis, but excluding pneumonia)

Chronic herpes simplex infection; (orolabial or cutaneous of more than one month's duration, or visceral at any site)

Extrapulmonary tuberculosis

Kaposi sarcoma

Esophageal candidiasis (or Candida of trachea, bronchi or lungs)

Cytomegalovirus (CMV) infection; retinitis or CMV infection affecting another organ, with onset at age over 1 month

Cental nervous system toxoplasmosis (after the neonatal period)

Extrapulmonary cryptococcosis (including meningitis)

HIV encephalopathy

Disseminated endemic mycosis (extrapulmonary histoplasmosis, coccidiomycosis)

Chronic cryptosporidiosis (with diarrhea)

Chronic isosporiasis

Disseminated non-tuberculous mycobacteria infection

Cerebral or B cell non-Hodgkin's lymphoma

Progressive multifocal leukoencephalopathy

HIV-associated cardiomyopathy or nephropathy

(i) Unexplained refers to where the condition is not explained by other causes.

(ii) Some additional specific conditions can be included in regional classifications (e.g. disseminated Penicilliosis in Asia, HIV associated rectovaginal fistula in Africa), and reactivation of American trypano somiasis.

Pictorial of Clinical Staging (Adapted from Bpai)⁴

Figure 4 shows the common manifestation of WHO clinical staging diseases.

Immune Staging of HIV Infection

CD4 counts and percentage values in healthy infants who are not infected with HIV are considerably higher than values than observed in uninfected adults and slowly decline to the adult values by five years. Clinicians interpreting CD4 must consider age as a variable. In children younger than age five years, the absolute CD4 count tends to vary more with age than does CD4 percentage. Therefore, HIV exposed infants and children younger than age 5 years, CD4 percentage is preferred for clinical assessment of degree of immune suppression and monitoring immune recovery, whereas absolute CD4 count can be used in older children (Table 2).

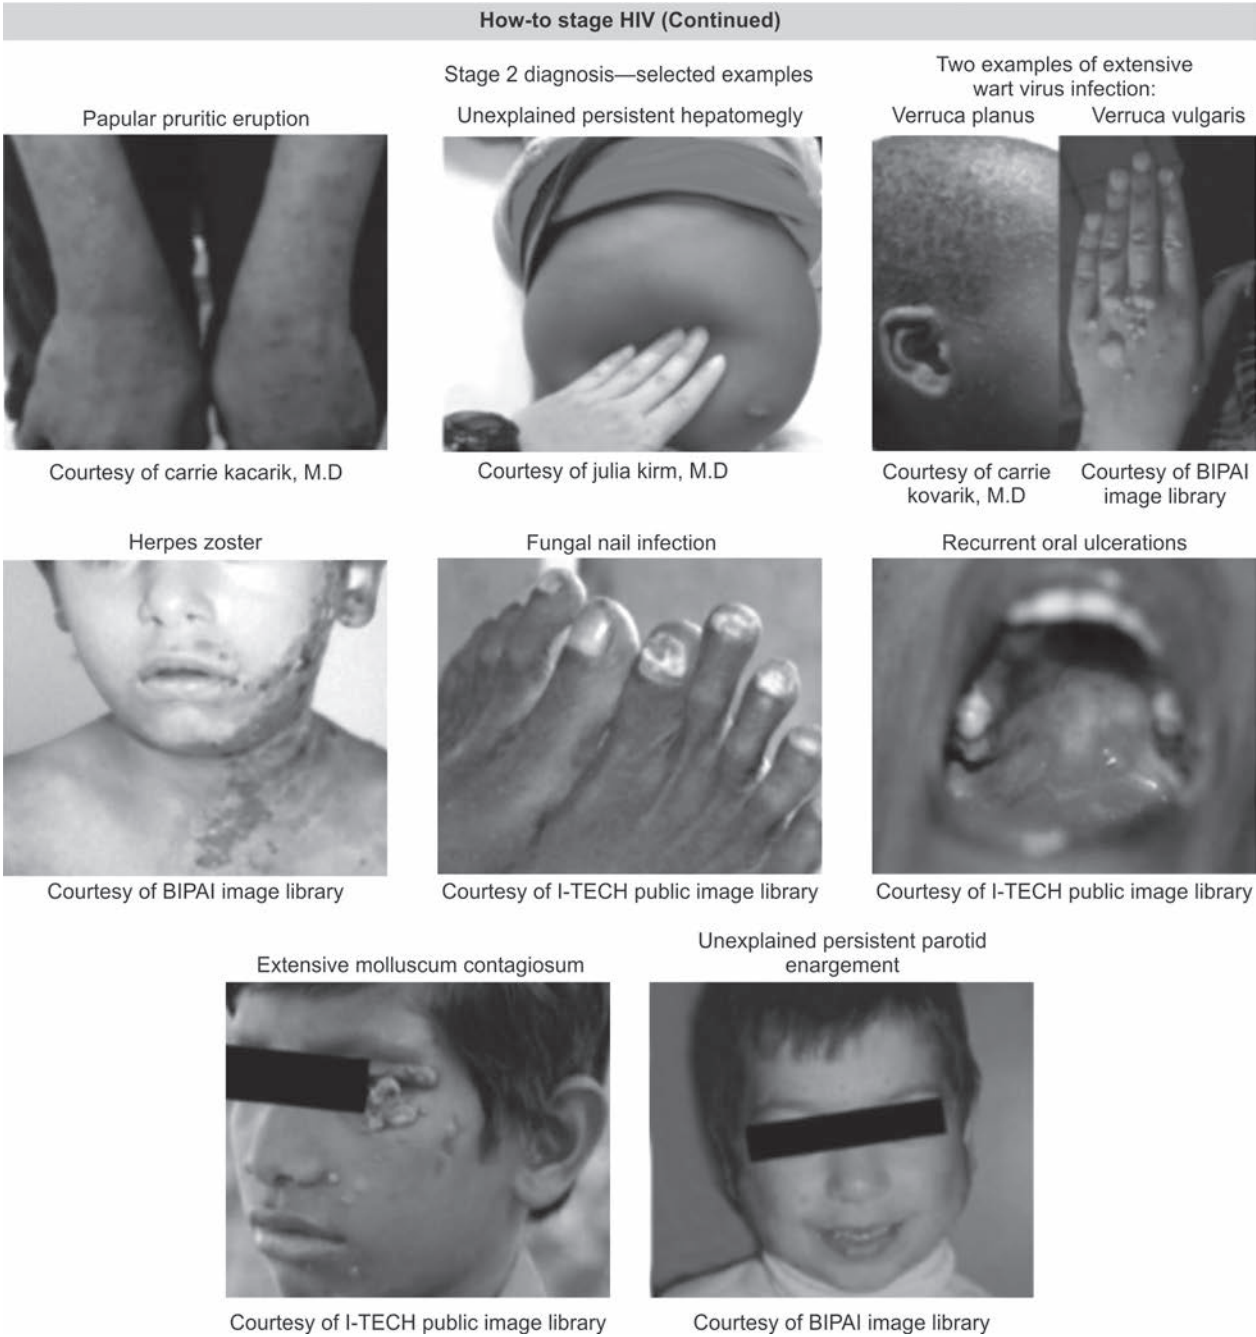

Fig. 4: Common manifestations of WHO clinical estaging diseases (For color version see plate 6)

Table 2: Classification of HIV associated immunodeficiency				
Classification of HIV-associated immunodeficiency	Age-related CD4 values			
	≤ 11 months (%)	12-35 months (%)	36-59 months (%)	≥ 5 years (cells/mm ³)
Not significant	> 35	> 30	> 25	> 500
Mild	30-35	25-30	20-25	350-499
Advanced	25-29	20-24	15-19	200-349
Severe	<25	<20	<15	<200 or <15%

Fig. 5: Estimated probability of AIDS within 12 months by age and CD4 percentage in HIV-infected children receiving no. Theory or zidovudine monotherapy [Modified from *Lancet* 2003;363; 1605-1611]

Fig. 6: Estimated probability of death within 12 months by age and CD4 percentage in HIV-infected children receiving no therapy or zidovudine monotherapy [Modified from *Lancet* 2003; 362; 1605-1611]

In HIV exposed children, as in infected adults, the CD4 count and percentage decline as HIV infection progresses, and patients with lower CD4 values have a poor prognosis than patients with higher values as shown by the study below.

The risk of disease progression associated with a specific CD4 percentage or count varies with age of the child. Infants in the first year of life experience higher risk of progression or death than older children for any given CD4 stratum. For example, comparing a one year old child with a CD4 percentage of 25 percent to a child of five years with same CD4 percentage, there is an approximately four fold increase in the risk of AIDS and a six fold increase in the risk of death in the one year old child (Figs 5 and 6).

KEY POINTS

- HIV disease is diagnosed using clinical signs and symptoms as well as specific laboratory tests.
- The HIV rapid test and HIV enzyme-linked immunosorbent assay are the screening tests used to detect HIV antibodies. These tests determine HIV exposure in infants younger than 18 months and diagnose HIV infection in children older than 18 months and in adults.
- Antibody tests cannot be used to definitively diagnose HIV in infants younger than 18 months because of passive placental transfer of maternal HIV immunoglobulin G antibody during pregnancy.

- Virologic testing (e.g., DNA polymerase chain reaction [PCR]) can be used to definitively diagnose HIV infection in infants younger than 18 months.
- Early diagnosis of HIV infection in infants on the basis of clinical signs and symptoms, rapid testing, and virologic testing is important to ensure timely enrolment of HIV-exposed infants into care, initiation of cotrimoxazole prophylaxis, and appropriate infant feeding counseling.
- Dried blood spot collection is highly stable and increases access to DNA PCR testing because of convenient sample handling and transport.
- If virologic testing is not readily available for infants younger than 18 months and an infant has a positive antibody test plus certain signs and symptoms of HIV, a presumptive diagnosis of HIV may be made and ARV therapy initiated as a potentially life-saving measure.

Annexure I

1994 Revised human immunodeficiency virus pediatric classification system: clinical categories**Category N: Not symptomatic*

Children who have no signs or symptoms considered to be the result of HIV infection or who have only one of the conditions listed in category A.

Category A: Mildly symptomatic

Children with two or more of the following conditions but none of the conditions listed in Categories B and C:

- Lymphadenopathy (≥ 0.5 cm at more than two sites; bilateral = one site)
- Hepatomegaly
- Splenomegaly
- Dermatitis
- Parotitis
- Recurrent or persistent upper respiratory infection, sinusitis, or otitis media

Category B: Moderately symptomatic

Children who have symptomatic conditions, other than those listed for Category A or Category C, that are attributed to HIV infection. Examples of conditions in Clinical Category B include but are not limited to, the following:

- Anemia (< 8 gm/dl), neutropenia ($< 1,000$ cells/mm³) or thrombocytopenia ($< 100,000$ cells/mm³) persisting ≥ 30 days
- Bacterial meningitis, pneumonia or sepsis (single episode)
- Candidiasis, oropharyngeal (i.e. thrush) persisting for > 2 months in children age > 6 months
- Cardiomyopathy
- Cytomegalovirus infection with onset before age 1 month
- Diarrhea, recurrent or chronic
- Hepatitis
- Herpes simplex virus (HSV) stomatitis, recurrent (i.e. more than two episodes within 1 year)
- HSV bronchitis pneumonitis, or esophagitis with onset before age 1 month
- Herpes zoster (i.e. shingles) involving at least two distinct episodes or more than one dermatome
- Leiomyosarcoma
- Lymphoid interstitial pneumonia (LIP) or pulmonary lymphoid hyperplasia complex
- Nephropathy
- Nocardiosis
- Fever lasting > 1 month
- Toxoplasmosis with onset before age 1 month
- Varicella, disseminated (i.e. complicated chickenpox)

Category C: Severely symptomatic

Children who have any condition listed in the 1987 surveillance case definition for acquired immunodeficiency syndrome (below), with the exception of LIP (which is a Category B condition):

- Serious bacterial infections, multiple or recurrent (i.e. any combination of at least two culture-confirmed infections within a 2-year period), of the following types: septicemia, pneumonia, meningitis, bone or joint infection, or abscess of an internal organ or body cavity (excluding otitis media, superficial skin or mucosal abscesses, and indwelling catheter-related infections)
- Candidiasis, esophageal or pulmonary (bronchi, trachea, lungs)
- Coccidioidomycosis, disseminated (at site other than or in addition to lungs or cervical or hilar lymph nodes)

Contd...

- Cryptococcosis, extrapulmonary
- Cryptosporidiosis or isosporiasis with diarrhea persisting > 1 month
- Cytomegalovirus disease with onset of symptoms at age > 1 month (at a site other than liver, spleen, or lymph nodes)
- Encephalopathy (at least one of the following progressive findings present for at least 2 months in the absence of a concurrent illness other than HIV infection that could explain the findings): (a) failure to attain or loss of developmental milestones or loss of intellectual ability, verified by standard developmental scale or neuropsychological tests; (b) impaired brain growth or acquired microcephaly demonstrated by head circumference measurements or brain atrophy demonstrated by computerized tomography or magnetic resonance imaging (serial imaging is required for children <2 years of age); (c) acquired symmetric motor deficit manifested by two or more of the following: paresis, pathologic reflexes, ataxia, or gait disturbance
- Herpes simplex virus infection causing a mucocutaneous ulcer that persists for > 1 month or bronchitis, pneumonitis, or esophagitis for any duration affecting a child > 1 month of age
- Histoplasmosis, disseminated (at a site other than or in addition to lungs or cervical or hilar lymph nodes)
- Kaposi's sarcoma
- Lymphoma, primary, in brain
- Lymphoma, small, noncleaved cell (Burkitt's), or immunoblastic or large cell lymphoma of B-cell or unknown immunologic phenotype
- *Mycobacterium tuberculosis*, disseminated or extrapulmonary
- *Mycobacterium*, other species or unidentified species, disseminated (at a site other than or in addition to lungs, skin, or cervical or hilar lymph nodes)
- *Mycobacterium avium* complex or *Mycobacterium kansasii*, disseminated (at site other than or in addition to lungs, skin, or cervical or hilar lymph nodes)
- *Pneumocystis jiroveci* pneumonia
- Progressive multifocal leukoencephalopathy
- *Salmonella* (nontyphoid) septicemia, recurrent
- Toxoplasmosis of the brain with onset at > 1 month of age
- Wasting syndrome in the absence of a concurrent illness other than HIV infection that could explain the following findings: (a) persistent weight loss > 10% of baseline; OR (b) downward crossing of at least two of the following percentile lines on the weight-for-age chart (e.g. 95th, 75th, 50th, 25th, 5th) in a child ≥1 year of age; OR (c) <5th percentile on weight-for-height chart on two consecutive measurements, ≥30 days apart PLUS (1) chronic diarrhea (i.e. ≥ two loose stools per day for ≥30 days), OR (2) documented fever (for >30 days, intermittent or constant)

* Centers for Disease Control and Prevention. 1994 Revised classification system for human immunodeficiency virus infection in children less than 13 years of age. MMWR. 1994. 43 (No. RR-12): D. 1-10.

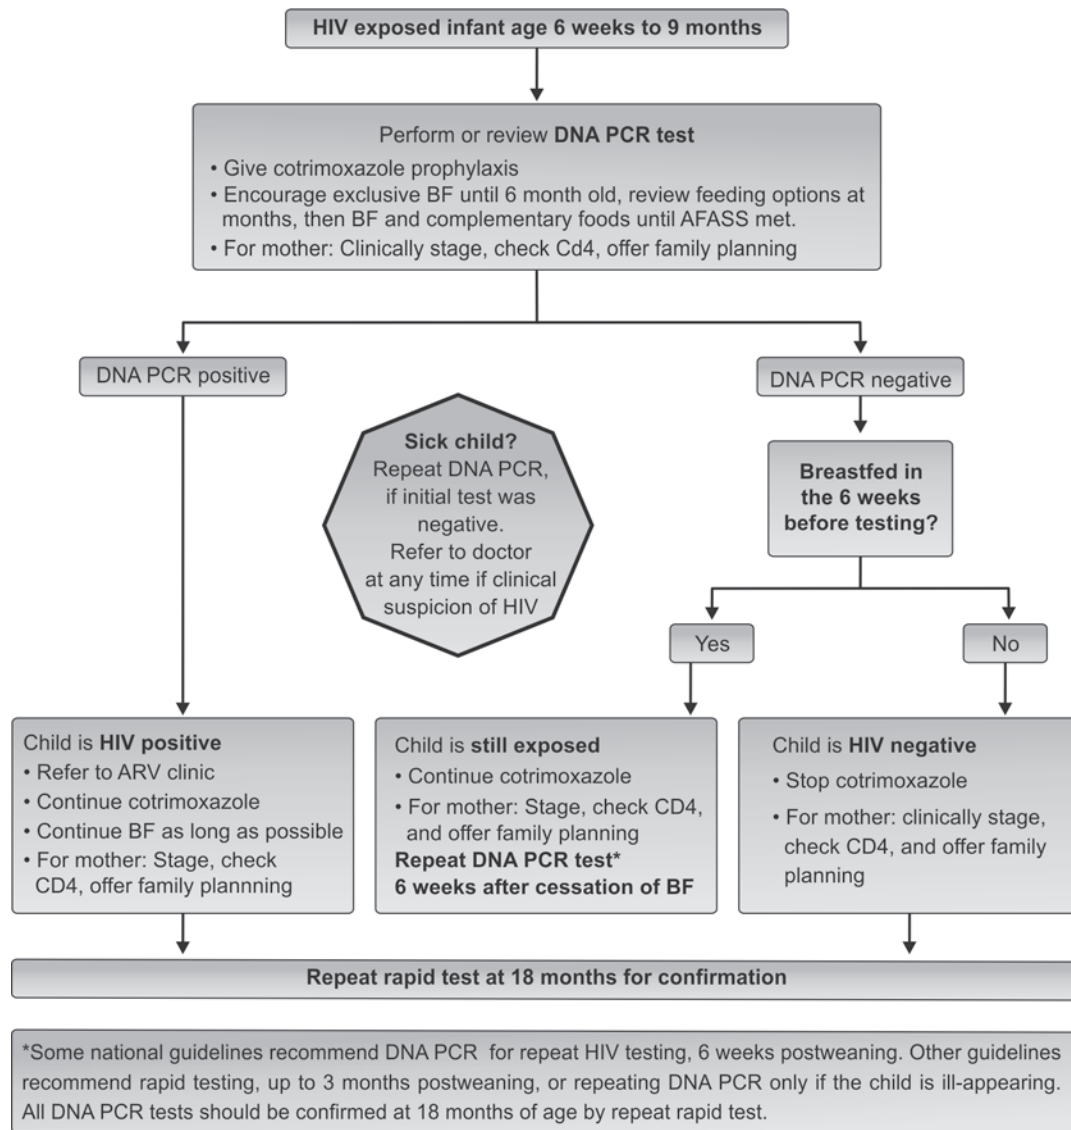

1994 Revised Human Immunodeficiency Virus Pediatric Classification System: Immune Categories Based on Age-Specific: CD4+ T-Lymphocyte Count and Percentage*

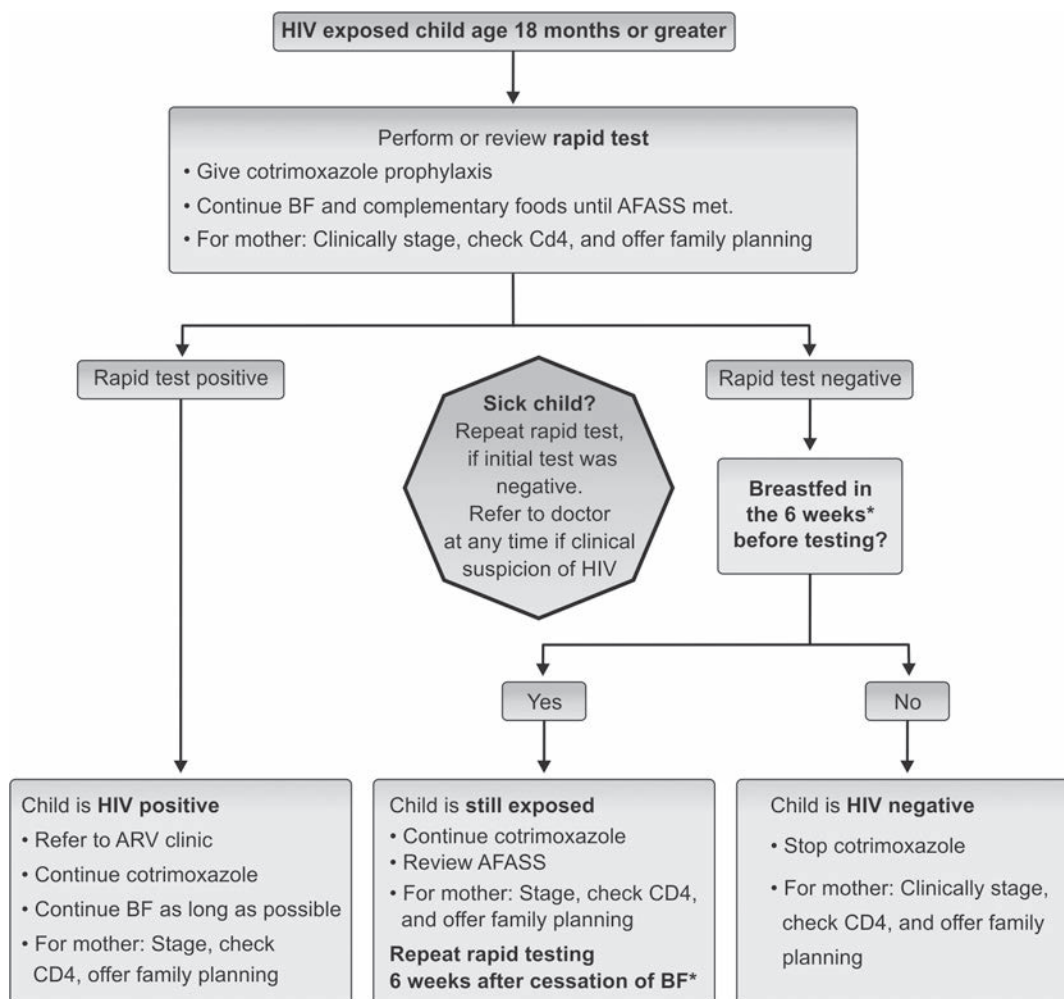

Immune Category	<12 months		1-5 years		6-12 years	
	No./uL	(%)	No./uL	(%)	No/uL	(%)
1: No suppression	>1500	(>25%)	>1000	(>25%)	>500	(>25%)
2: Moderate suppression	750-1499	(15-24%)	500-999	(15-24%)	200-499	(15-24%)
3: Severe suppression	<750	(<15%)	<500	(<15%)	<200	(<15%)

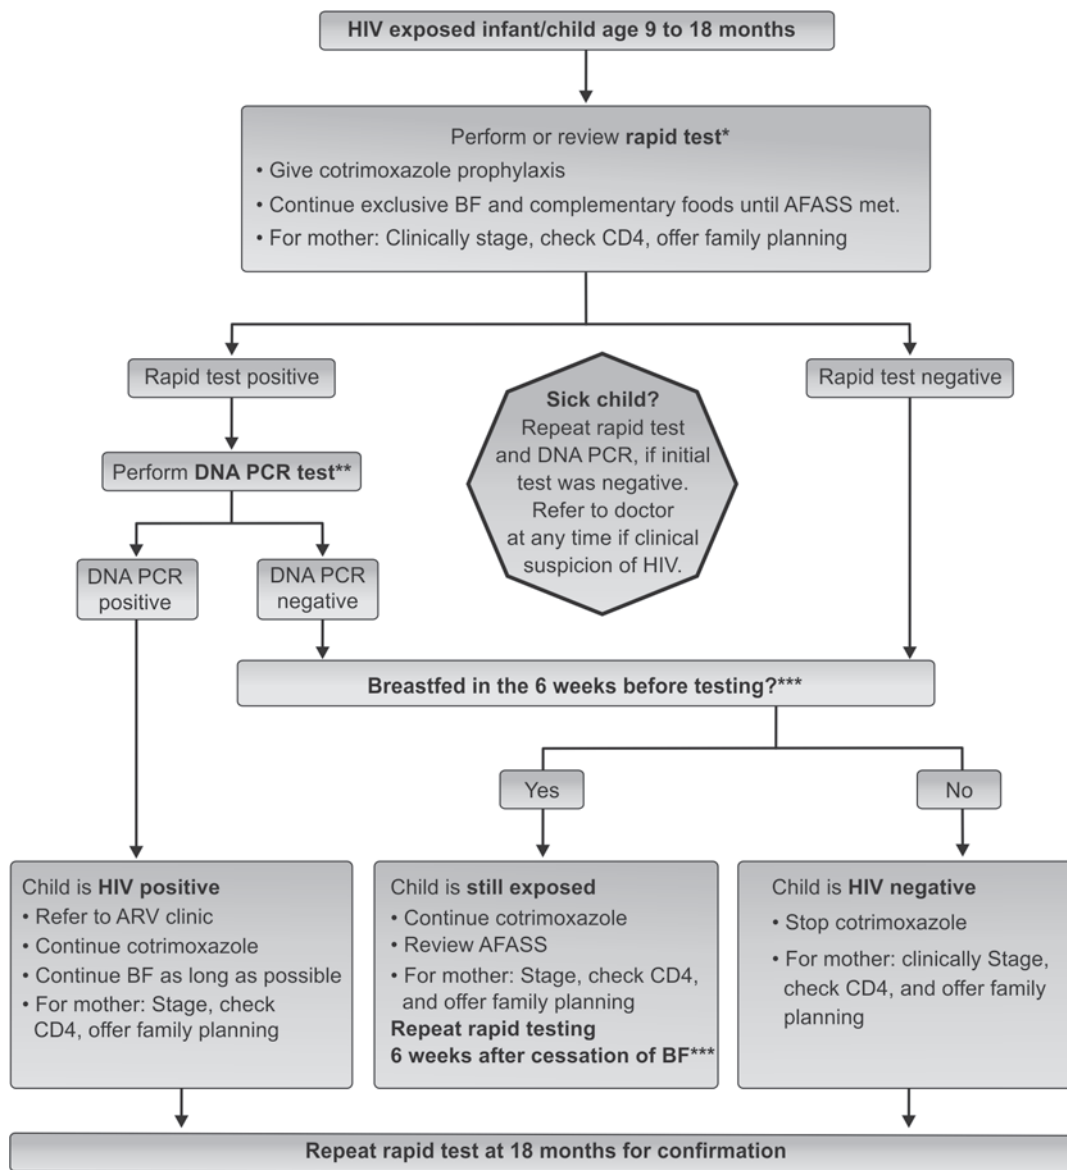

* Modified for CDC, 1994. Revised classification system for human immunodeficiency virus infection in children less than 13 years of age. MMWR 1994;43 (no. RR-12):1-10.

Annexure II

HIV Diagnosis in exposed infants and young children

*WHO recommends that, from 9 months of age, antibody tests are performed first to ensure that virologic testing is only done on children who still have HIV antibodies. The use of a rapid tests in the 9-18 month age group varies by country.

** While awaiting DNA PCR results, CD4 evaluation is recommended in most settings due to a high likelihood of true infection. Clinical judgement should be used to determine if a patient should be referred to an ARV clinic at this time

*** WHO recommends using a 6 weeks window period for rapid testing after 9 months of age. Several national guidelines use a 3 months window period for rapid testing. All DNA PCR tests should be confirmed at 18 months of age by repeat rapid test

Integrated Management of Childhood illness (IMCI) is a WHO/UNICEF strategy; aimed at reducing mortality in children under five years by improving health care at a primary level. IMCI was introduced in 1995 and has been implemented in over 100 countries worldwide. IMCI provides a series of guidelines, often in the form of screening questions and symptom checklists, for assessing and treating common causes of childhood morbidity and mortality on the primary (Me level). IMCI has been adapted to include an algorithm to identify children with symptomatic HIV infection at the primary care level. Though this algorithm is useful where laboratory testing is not available, it fails to identify large portion of infected children and should not be used alone for HIV diagnosis.

Source: Adapted from "Integrated Management of Childhood Illness for High HIV Settings", WHO 2006

WHO case definitions for HIV-related disease (continued.)

<i>Clinical event</i>	<i>Clinical appearance</i>	<i>Clinical stage 3 (continued)</i>	<i>How to diagnose</i>
Oral candidiasis (after the first 6-8 weeks of life)	Persistent or recurring creamy white to yellow soft small plaques which can be scraped off (pseudomembranous), or red patches on tongue, palate or lining of mouth, usually painful or tender (erythematous form)		Microscopy or culture
Oral hairy leukoplakia	Fine small linear patches on lateral borders of tongue, generally bilateral that do not scrape off		Clinical diagnosis
Acute necrotizing ulcerative gingivitis or stomatitis, or periodontitis	Severe pain, ulcerated gingival papillae, loosening of teeth, spontaneous bleeding, bad odor, and rapid loss of bone and/or soft tissue.		Clinical diagnosis
Lymph node tuberculosis	Nonacute, painless "cold" enlargement of peripheral lymph nodes, localized to one region. Response to standard anti-TB treatment in one month.		Histology or fine needle aspirate positive for Ziehl-Nielsen stain or culture.
Pulmonary TB	Nonspecific symptoms, such as chronic cough, fever, night sweats, anorexia and wt loss. In the older child, also productive cough and hemoptysis. History of contact with adults with smear-positive pulmonary TB. No response to standard broad-spectrum antibiotic treatment.		One or more sputum smear-positive for acid-fast bacilli and/or radiographic abnormalities c/w active TB and/or culture-positive for <i>Mycobacterium</i> .
Severe recurrent bacterial pneumonia	Cough with fast breathing, chest indrawing, nasal flaring, wheezing and grunting. Crackles or con solidation on auscultation. Responds to course of antibiotics. Current episode plus one or more in previous 6 months.		Isolation of bacteria from appropriate clinical specimens (included sputum, bronchoalveolar lavage and lung aspirate)
Symptomatic lymphocytic interstitial pneumonia	No presumptive clinical diagnosis		CXR: bilateral reticulonodular interstitial pulmonary infiltrates present for more than 2 months with no response to antibiotic treatment and no other pathogen found. O ₂ saturations: <90%, persistently. Cor pulmonale and increased exercise-induced fatigue. Characteristic histology.
Chronic HIV-associated lung disease (including bronchiectasis)	History of cough productive of copious amounts of purulent sputum (bronchiectasis only), with or without clubbing, halitosis, and crepitations and/or wheezes on auscultation		CXR may show honeycomb appearance (small cysts) and/or persistent area of opacification and/or widespread lung destruction, with fibrosis and loss of volume.
Unexplained anemia (<8 g/dl), neutropenia (<0.5 × 10 ⁹ /L and or chronic thrombocytopenia (<50 × 10 ⁹ /L)	No presumptive clinical diagnosis		Lab testing, not explained by other non-HIV conditions, not responding to standard therapy with hematinics, antimalarial, or antihelminthic agents as outlined in WHO IMCI guidelines.
CLINICAL STAGE 4			
Unexplained severe wasting, stunting, or severe malnutrition not adequately responding to standard therapy	Persistent wt loss not explained by poor or inadequate feeding; other infections, and not adequately responding in 2 wks to standard therapy. Visible severe wasting of muscles with or without edema of both feet, and/or wt-for-ht of -3 SD from the mean, as defined by WHO IMCI guidelines		Documented loss of over more than - 3 SD from the mean with or without edema.
Pneumocystis pneumonia	Dry cough, progressive difficulty in breathing, cyanosis, tachypnea and fever; chest indrawing or stridor. (Severe or very severe pneumonia as in WHO IMCI guidelines). Rapid onset especially in infants younger than 6 months of age. Response to high-dose cotrimoxazole with or without prednisolone. CXR shows typical bilateral perihilar diffuse infiltrates.		Cytology or immunofluorescent microscopy of induced sputum or bronchoalveolar lavage (BAL) or histology of lung tissue

Contd...

Contid...

Clinical event	Clinical appearance	How to diagnose
<i>Clinical State 4</i>		
Recurrent severe bacterial infection, i.e. empyema, pyomyositis, bone/joint infection, meningitis, but excluding pneumonia	Fever accompanied by specific symptoms or signs that localize infection. Responds to antibiotics. Current episode plus 1 or more in previous 6 months.	Culture of appropriate clinical specimen.
Chronic herpes simplex infection; (orolabial/cutaneous of more than 1 month's, duration or visceral at any site)	Severe and progressive painful orolabial, genital, or anorectal lesions caused by herpes simplex virus infection present for more than 1 month.	Culture and/or histology
Esophageal candidiasis (or candidiasis of trachea, bronchi, lungs)	Difficulty in swallowing, or pain on swallowing (food and fluids). In young children, suspect particularly if oral Candida observed and food refusal occurs and or difficulty or crying when feeding.	Macroscopic appearance at endoscopy, microscopy of specimen from tissue or macroscopic appearance at bronchoscopy or histology
Extrapulmonary or disseminated TB	Systemic illness usually with prolonged fever, night sweats and wt loss. Clinical features of organs involved, such as sterile pyuria pericarditis, ascites, pleural effusion, meningitis, arthritis, or orchitis, pericardial or abdominal	Positive microscopy showing acid-fast bacilli or culture of <i>Mycobacterium tuberculosis</i> from blood or other relevant specimen except sputum of BAL. Biopsy and histology.
Kaposi sarcoma	Typical appearance in skin or oropharynx of persistent, initially flat, patches with a pink or blood-ruise color, skin lesions that usually develop into nodules.	Not required but may be confirmed by: (1) typical red-purple lesions seen on bronchoscopy/endoscopy; (2) dense masses in lymph nodes, viscera, or lungs by palpation or radiology and (3) histology.
CMV retinitis or CMV infection affecting another organ, with onset older than 1 month of age	CMV retinitis may be diagnosed by experienced clinicians: typical eye lesions on serial fundoscopic exam: discrete patches of retinal whitening with distinct borders, spreading centrifugally, often following blood vessels, associated with retinal vasculitis, hemorrhage necrosis.	Definitive diagnosis required for other sites. Histology. CSF PCR.
CNS toxoplasmosis, onset after 1 month of age	Fever, headache, focal nervous system signs and convulsions. Usually responds within 10 days to specific therapy.	Computed tomography scan (or other neuroimaging) showing single or multiple lesions with mass effect or enhancing with contrast.
Extrapulmonary cryptococcosis, (including meningitis)	Meningitis: Usually subacute, fever with increasing severe headache, meningism, confusion behavioral changes that respond to cryptococcal therapy	CSF microscopy (India ink or Gram stain), serum or CSF cryptococcal antigen test or culture

CHAPTER 46

Postexposure Prophylaxis and Prevention of Parent to Child Transmission

Ajay Arora, SP Yadav, Anupam Sachdeva, Nivedita Dhingra

ABBREVIATIONS AND ACRONYMS

AEB: accidental exposure to blood
ART: antiretroviral therapy
ARV: antiretroviral (drug)
AZT: zidovudine (also known as zdv)
d4T: stavudine
ddI: didanosine
EFV: efavirenz
HBV: hepatitis B virus
HCP: health care professional
HCV: hepatitis C virus
NNRTI: nonnucleoside reverse transcriptase inhibitor
NRTI: nucleoside analog reverse transcriptase inhibitor
PLHA: people living with HIV/AIDS
SQV: saquinavir

OCCUPATIONAL EXPOSURE

Occupational exposure refers to exposure to potential blood-borne infections (HIV, HBV and HCV) that may occur in health care settings during performance of job duties. Postexposure prophylaxis (PEP) refers to comprehensive medical management to minimize the risk of infection among health care personnel (HCP) following potential exposure to blood-borne pathogens (HIV, HBV, HCV). This includes counseling, risk assessment, relevant laboratory investigations based on informed consent of the source and exposed person, first aid and depending on the risk assessment, the provision of short-term (four weeks) of antiretroviral drugs, with follow-up and support.

What is the Risk?

Health care personnel are at risk of blood-borne infection transmission through exposure of a percutaneous injury (e.g. needle-stick or cut with a sharp instrument), contact

with the mucous membranes of the eye or mouth of an infected person, contact with nonintact skin (particularly when the exposed skin is chapped, abraded, or afflicted with dermatitis) or contact with blood or other potentially infectious body fluids.

Any direct contact (i.e. contact without barrier protection) with concentrated virus in a research laboratory or production facility requires clinical evaluation. Transmission of HIV infection from human bites is rarely reported.

The average risk of acquiring HIV infection from different types of occupational exposure is low compared to risk of infection with HBV or HCV. In terms of occupational exposure the important routes are needle-stick exposure (0.3% risk for HIV, 9-30% for HBV and 1-10% for HCV) and mucous membrane exposure (0.09% for HIV).

What is infectious and what is not?

Exposure to blood, semen, vaginal secretions, cerebrospinal fluid, synovial, pleural, peritoneal, pericardial fluid, amniotic fluid and other body fluids contaminated with visible blood can lead to infection. Exposure to tears, sweat, saliva, urine and feces is noninfectious unless these secretions contain visible blood.

FIRST AID IN MANAGEMENT OF EXPOSURE

For skin — if the skin is broken after a needle-stick or sharp instrument:

- Immediately wash the wound and surrounding skin with water and soap, and rinse. Do not scrub.
- Do not use antiseptics or skin washes (bleach, chlorine, alcohol, betadine)
- *After a splash of blood or body fluids on unbroken skin:*
- Wash the area immediately
- Do not use antiseptics

For the eye:

- Irrigate exposed eye immediately with water or normal saline. Sit in a chair, tilt head back and ask a colleague to gently pour water or normal saline over the eye.
- If wearing contact lens, leave them in place while irrigating, as they form a barrier over the eye and will help protect it. Once the eye is cleaned, remove the contact lens and clean them in the normal manner. This will make them safe to wear again
- Do not use soap or disinfectant on the eye.

For mouth:

- Spit fluid out immediately
- Rinse the mouth thoroughly, using water or saline and spit again. Repeat this process several times
- Do not use soap or disinfectant in the mouth
- Consult the designated physician of the institution for management of the exposure immediately.

Don'ts

- Do not panic
- Do not put pricked finger in mouth
- Do not squeeze wound to bleed it
- Do not use bleach, chlorine, alcohol, betadine, iodine or any antiseptic or detergent

Establish Eligibility for PEP

The HIV seroconversion rate of 0.3 percent after an AEB (for percutaneous exposure) is an average rate. The risk of infection transmission is proportional to the amount of HIV transmitted, which depends on the nature of exposure and the status of the source patient. A baseline rapid HIV testing of exposed and source person must be done for PEP. However, initiation of PEP should not be delayed while waiting for the results of HIV testing of the source of exposure. Informed consent should be obtained before testing of the source as per national HIV testing guidelines.

First PEP dose within 72 hours

A designated person/trained doctor must assess the risk of HIV and HBV transmission following an AEB. This evaluation must be quick so as to start treatment without any delay, ideally within two hours but certainly within 72 hours; PEP is not effective when given more than 72 hours after exposure. The first dose of PEP should be administered within the first 72 hours of exposure. If the risk is insignificant, PEP could be discontinued, if already commenced.

ASSESSING RISK OF TRANSMISSION

Exposure is defined under three categories based on the amount of blood/ fluid involved and the entry port. These categories are intended to help in assessing the severity of the exposure but may not cover all possibilities (Table 1).

Table 1: Categories of exposure

Mild exposure	Mucous membrane/nonintact skin with small volumes For example, a superficial wound (erosion of the epidermis) with a plain or low caliber needle, or contact with the eyes or mucous membranes, subcutaneous injections following small-bore needles.
Moderate exposure	Mucous membrane/nonintact skin with large volumes or percutaneous superficial exposure with solid needle For example, a cut or needlestick injury penetrating gloves
Severe exposure	Percutaneous with large volume e.g. an accident with a high caliber needle (>18 G) visibly contaminated with blood; a deep wound (hemorrhagic wound and/or very painful); transmission of a significant volume of blood; an accident with material that has previously been used intravenously or intra-arterially.

The wearing of gloves during any of these accidents constitutes a protective factor.

Note: In case of an AEB with material such as discarded sharps/needles, contaminated for over 48 hours, the risk of infection is negligible for HIV, but still remains significant for HBV. HBV survives longer than HIV outside the body.

Counseling for PEP

Exposed persons should receive appropriate information about what PEP is about and the risk and benefits of PEP in order to provide informed consent for taking PEP. It should be clear that PEP is not mandatory.

Psychological Support

Many people feel anxious after exposure. Every exposed person needs to be informed about the risks, and the measures that can be taken. This will help to relieve part of the anxiety. Some clients may require further specialised psychological support.

Document Exposure

Documentation of exposure is essential. Special leave from work should be considered initially for a period of two weeks. Subsequently, it can be extended based on the assessment of the exposed person's mental state, side effects and requirements.

Deciding on PEP Regimen

There are two types of regimens:

Basic regimen: Two-drug combination

Expanded regimen: Three-drug combination

Table 2: HIV PEP evaluation

Exposure	Status of source		
	HIV+ and Asymptomatic	HIV+ and Clinically symptomatic	HIV status unknown
Mild	Consider 2-drug PEP	Start 2-drug PEP	Usually no PEP or consider 2-drug PEP
Moderate	Start 2-drug PEP	Start 3-drug PEP	Usually no PEP or consider 2-drug PEP
Severe	Start 3-drug PEP	Start 3-drug PEP	Usually no PEP or consider 2-drug PEP

The decision to initiate the type of regimen depends on the type of exposure and HIV serostatus of the source person (Table 2).

In the case of a high risk exposure from a source patient who has been exposed to or is taking antiretroviral medications, consult an expert to choose the PEP regimen, as the risk of drug resistance is high. Refer/consult expert physician. Start 2-drug regimen first.

Seek expert opinion in case of:

- Delay in reporting exposure (>72 hours)
- Unknown source
- Known or suspected pregnancy, but initiate PEP
- Breastfeeding mothers, but initiate PEP
- Source patient is on ART
- Major toxicity of PEP regimen

HIV CHEMOPROPHYLAXIS

Because postexposure prophylaxis (PEP) has its greatest effect if begun within two hours of exposure, it is essential to act immediately. The prophylaxis needs to be continued for four weeks. Exposure must be immediately reported to designated authority and therapy administered. Never delay start of therapy due to debate over regimen. Begin

with basic 2-drug regimen, and once expert advice is obtained, change as required (Tables 3 and 4).

Selection of PEP regimen when the source patient is on ART:

The physician should consider the comparative risk represented by the exposure taking in view exposure source's history of and response to antiretroviral therapy based on clinical response, CD4 cell counts, viral load measurements (if available), and current disease stage (WHO clinical staging and history). If the source person's virus is known or suspected to be resistant to one or more drugs considered for the PEP regimen, exposed person needs to be given alternate PEP drug regimen, and referred for expert opinion.

Changes in the PEP regimen can be made after PEP has been started. Re-evaluation of the exposed person should be considered within 72 hours postexposure, especially as additional information about the exposure or source person becomes available.

ARV DRUGS DURING PREGNANCY

Data regarding the potential effects of antiretroviral drugs on the developing fetus or neonate are limited. There is

Table 3: Dosage of drugs for PEP

Medication	2-drug regimen	3-drug regimen
Zidovudine (AZT)	300 mg twice a day	300 mg twice a day
Stavudine (d4T)	30 mg twice a day	30 mg twice a day
Lamivudine (3TC)	150 mg twice a day	150 mg twice a day
Protease inhibitors		<p><i>1st choice</i></p> <p>Lopinavir/ritonavir (LPV/ r) 400/ 100 mg twice a day or 800/ 200 mg once daily with meals</p> <p><i>2nd choice</i></p> <p>Nelfinavir (NLF)</p> <p>1250 mg twice a day or 750 mg three times a day with empty stomach</p> <p><i>3rd choice</i></p> <p>Indinavir (IND)</p> <p>800 mg every 8 hours and drink 8-10 glasses (1.5 liters) of water daily</p>

Note: If protease inhibitor is not available and the 3rd drug is indicated, one can consider using Efavirenz (EFV 600 mg once daily).

Monitoring should be instituted for side effects of this drug, e.g. CNS toxicity such as nightmares, insomnia, etc.

* Fixed dose combination (FDC) are preferred, if available. Ritonavir requires refrigeration.

Table 4: PEP regimens to be prescribed by health centers

	<i>Preferred</i>	<i>Alternative</i>
<i>2-drug regimen (basic PEP regimen)</i>	Zidovudine (AZT) + Lamivudine (3TC)	Stavudine (d4T) + Lamivudine (3TC)
<i>3-drug regimen (consult expert opinion for starting 3-drug, e.g. LPV/r, NLF or IND regimen)</i>		
<i>Not recommended</i>	ddI + d4T combination NNRTI such as Nevirapine should not be used in PEP	

a clear contraindication for Efavirenz (first 3 months of pregnancy) and Indinavir (prenatal).

For a female HCP considering PEP, a pregnancy test is recommended in case of a doubt. Pregnant HCP are recommended to begin the basic 2-drug regimen, and if a third drug is needed, Nelfinavir is the drug of choice.

SIDE EFFECTS AND ADHERENCE TO PEP

Studies have indicated more side effects, most commonly nausea and fatigue, among HCP taking PEP than PLHAs taking ART. These side effects occur mainly at the beginning of the treatment and include nausea, diarrhea, muscular pain and headache. The person taking the treatment should be informed that these may occur and should be dissuaded from stopping the treatment as most side-effects are mild and transient, though possibly uncomfortable. Anemia and/or leukopenia and/ or thrombocytopenia may occur during the month of treatment.

Adherence information and psychological support are essential. More than 95 percent adherence is important in order to maximize the efficacy of the medication in PEP. Side effects can be reduced through medications. A complete blood count and liver function tests (transaminases) may be performed at the beginning of treatment (as baseline) and after 4 weeks.

FOLLOW-UP OF AN EXPOSED PERSON

Whether or not postexposure prophylaxis is started, a follow up is needed to monitor for possible infections and to provide psychological support.

Clinical Follow-up

In the weeks following an AEB, the exposed person must be monitored for the eventual appearance of signs indicating an HIV seroconversion: acute fever, generalized lymphadenopathy, cutaneous eruption, pharyngitis, non-specific flu symptoms and ulcers of the mouth or genital area. These symptoms appear in 50 to 70 percent of individuals with an HIV primary (acute) infection and almost always within 3 to 6 weeks after exposure. When a primary (acute) infection is suspected, referral to an ART center or for expert opinion should be arranged rapidly.

An exposed person should be advised to use precautions (e.g. avoid blood or tissue donations, breastfeeding, unprotected sexual relations or pregnancy) to prevent secondary transmission, especially during the first 6 to 12 weeks following exposure. Condom use is essential.

Drug adherence and side effect counseling should be provided and reinforced at every follow-up visit. Psychological support and mental health counseling is often required.

Laboratory Follow-up

Exposed persons should have post-PEP HIV tests. HIV-test at 3 months and again at 6 months is recommended. If the test at 6 months is negative, no further testing is recommended.

PREVENTION OF PARENT TO CHILD TRANSMISSION (FLOW CHART 1)

Mother to child transmission (MTCT) is by far the most significant route of transmission of HIV infection in children below the age of 15 years. HIV can be transmitted during pregnancy, during childbirth, or breastfeeding. Without intervention, the risk of transmission from an infected mother to her child ranges from 15 to 25 percent in developed countries and from 25 to 45 percent in developing countries. This difference is largely attributed to breast-feeding practices (Table 5).

The prevention of parent to child transmission (PPTCT) of HIV/AIDS programme was started in the country in the year 2002 following a feasibility study in 11 major hospitals in the five high HIV prevalence states. Currently, there are more than 4000 Integrated Counseling

Table 5: Estimated risk and timing of MTCT in the absence of interventions

During pregnancy	5-10%
During labor and delivery	10-15%
During breastfeeding	5-20%
Overall without breastfeeding	15-25%
Overall with breastfeeding to 6 months	20-35%
Overall with breastfeeding to 18 to 24 months	30-45%

and Testing Centers (ICTCs) in the country, most of these in government hospitals, which offer PPTCT services to pregnant women. Of these ICTCs, 502 are located in obstetrics and gynecology departments and in maternity homes where the client load is predominantly comprised of pregnant women.

The Joint Technical Mission on PPTCT (2006) estimated that out of 27 million annual pregnancies in India, 189,000 occur in HIV positive pregnant women. In the absence of any intervention, an estimated cohort of 56,700 infected babies will be born annually. *The PPTCT programme aims to prevent the perinatal transmission of HIV from an HIV infected pregnant mother to her newborn baby.* The program entails counseling and testing of pregnant women in the ICTCs. Pregnant women who are found to be HIV positive are given a single dose of Nevirapine at the time of labor; their newborn babies also get a single dose of Nevirapine immediately after birth so as to prevent transmission of HIV from mother-to-child.

Significant progress is being made in the global scale-up of prevention of mother-to-child transmission of HIV (PMTCT), including in high burden and resource-limited settings. For the first time, the elimination of mother-to-child transmission of HIV (MTCT) is now considered a realistic public health goal and an important part of the campaign to achieve the millennium development goals.

CARE OF THE MOTHER

Pregnancy is a special situation which provides a unique opportunity for the prevention of vertical transmission of HIV using various interventions. The risk of transmission of HIV from an infected mother is 14 to 32 percent if the child is not breastfed, and 25 to 48 percent if the child is breastfed. More than two-thirds of such transmission occurs during labor, when the baby is exposed to maternal genital fluids, and a significant proportion occurs through breastfeeding. Women who are HIV positive are at increased risk of opportunistic infections such as tuberculosis, herpes simplex, cytomegalovirus and invasive bacterial infections such as *Streptococcus pneumoniae* and salmonellosis.

The goals of management of HIV in pregnancy are dual: managing the mother's HIV status and prevention of mother-to-child transmission (PMTCT). The indications for ART and drug selection in pregnancy are similar to those in nonpregnant women. However, in the selection of a drug regimen, the following points should be remembered:

- AZT should be included as one of the components of the regimen unless there are absolute contraindications for using it.
- EFV should be avoided in the first-trimester of pregnancy (because of the risk of teratogenicity)
- When NVP is used and the mother's CD4 count is $>250/\text{mm}^3$, close monitoring of liver function is required.

When women who are already on ART become pregnant, the benefits and risks of ART in the first-trimester need to be considered. The benefits are a reduction in the risk of developing resistance and a decrease in the risk to the mother. The risk of continuing ART consists of the potential for ARV fetal toxicity, particularly during the first trimester of pregnancy. Good clinical management of HIV in pregnant women requires the support of a multidisciplinary team, including antenatal specialists, pediatricians, counselors, members of the ART center and community-based organizations (NGOs, positive network, etc.)

The criteria for initiating ART in pregnant women are the same as for other adults:

- WHO clinical stage 3 or 4 disease
- WHO clinical stage 1 or 2 disease and $\text{CD4} < 200 \text{ cells}/\text{mm}^3$
- WHO stage 3 disease and $\text{CD4} < 350 \text{ cells}/\text{mm}^3$

The initiation of ART helps prevent transmission of HIV to the newborn and also benefits the mother's own health. Once initiated, it should be continued postpartum.

The preferred NRTIs for use in pregnant women are AZT and 3TC. The combination of ddI and d4T should not be used because of associated increased toxicities in pregnant women. Studies have shown that TDF is associated with decreased fetal growth and bone demineralization. The preferred NNRTI is NVP, with which there has been extensive clinical experience globally. Its efficacy in reducing mother-to-child transmission has been proven. SQV/ r and Nelfinavir (NLF) are the preferred PI's if the woman needs to take PIs. EFV may be considered after the first-trimester.

The consistent use of condoms is recommended for all HIV infected women who are on ART. This is for the prevention of secondary transmission of HIV from/to the partner, as well as the prevention of unplanned pregnancy. *Antiretroviral treatment options recommended for HIV infected pregnant women who are eligible for treatment:*

Maternal ART + infant ARV prophylaxis

Mother

Maternal antepartum daily ART, starting as soon as possible irrespective of gestational age, and continued during pregnancy, delivery and thereafter. Recommended regimens include:

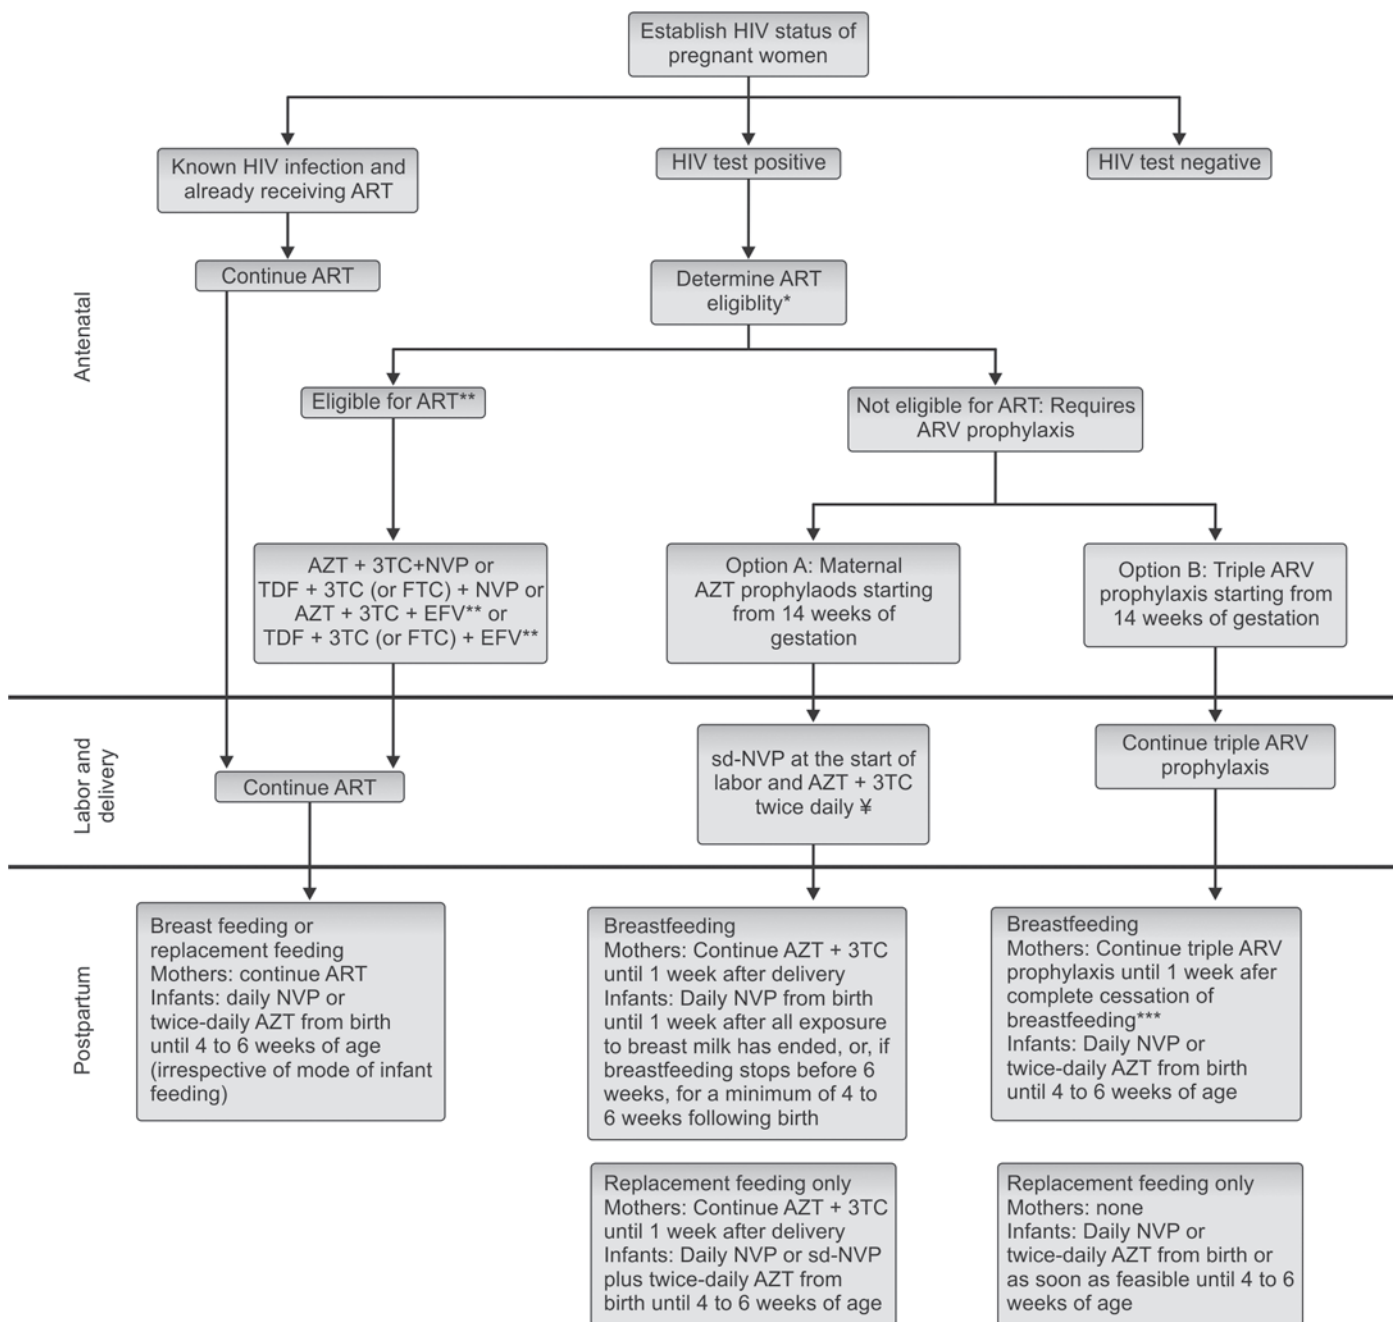

AZT + 3TC + NVP or
AZT + 3TC + EFV* or
TDF + 3TC (or FTC) + NVP or
TDF + 3TC (or FTC) + EFV*

Infant

Daily NVP or twice-daily AZT from birth until 4 to 6 weeks of age (irrespective of the mode of infant feeding)

* Avoid use of EFV in the first-trimester and use NVP instead.

ARV-prophylaxis options recommended for HIV infected pregnant women who do not need treatment for their own health (Table 6).

Flow Chart 1: Algorithm for the 2010 PMTCT recommendations

*Start ARV prophylaxis while waiting to determine ART eligibility

** Avoid use of EFV in first-trimester use NVP instead

*** When stopping any NNRTI-based regimen, stop the NNRTI first and continue the two NRTIs for 7 days and then stop them to reduce the chance of NNRTI resistance.

¥ FAZT was taken for at least the last 4 weeks before delivery, omission of the maternal sd-NVP and accompanying tail (AZT-3TC) can be considered. In this case, continue maternal AZT twice daily during labor and stop at delivery.

Care of the Infant at Birth

HIV infection is difficult to diagnose in infants, as most infected babies appear healthy and exhibit no signs and symptoms at birth. Maternal predictors of infant disease

progression include maternal viral load, maternal CD4 count (<200), rapidly progressing maternal disease, maternal death. Care of the neonate and infants will need to include adequate referral linkages between the maternal and child units and adult care facilities.

Table 6: ARV prophylaxis options for HIV infected pregnant women

<i>Maternal AZT + infant ARV prophylaxis (Option A)</i>	<i>Maternal triple ARV prophylaxis (Option B)</i>
<i>Mother</i>	<i>Mother</i>
Antepartum twice-daily AZT starting from as early as 14 weeks of gestation and continued during pregnancy. At onset of labor, sd-NVP and initiation of twice daily AZT + 3TC for 7 days postpartum. (Note: If maternal AZT was provided for more than 4 weeks antenatally, omission of the sd-NVP and AZT + 3TC tail can be considered; in this case, continue maternal AZT during labor and stop at delivery).	Triple ARV prophylaxis starting from as early as 14 weeks of gestation and continued until delivery, or, if breastfeeding, continued until 1 week after all infant exposure to breast milk has ended. Recommended regimens include: AZT + 3TC + LPV/r or AZT + 3TC + ABC or AZT + 3TC + EFV or TDF + 3TC (or FTC) + EFV
<i>Infant</i>	<i>Infant</i>
<i>For breastfeeding infants</i> Daily NVP from birth for a minimum of 4 to 6 weeks, and until 1 week after all exposure to breast milk has ended. <i>Infants receiving replacement feeding only</i> Daily NVP or sd-NVP + twice-daily AZT from birth until 4 to 6 weeks of age.	<i>Irrespective of mode of infant feeding</i> Daily NVP or twice daily AZT from birth until 4 to 6 weeks of age

Definition of HIV-exposure: Infants and children born to mothers living with HIV, until HIV infection in the infant or child is reliably excluded and the infant or child is no longer exposed through breastfeeding. Care of HIV-exposed infants should follow standard neonatal care according to safe motherhood guidelines including the following:

- The baby's mouth and nostrils should be wiped as soon as the head is delivered
- Infants should be handled with gloves until all blood and maternal secretions have been washed off (early baby bathing)
- The cord should be clamped soon after birth, but milking should be avoided. Cover the cord with gloved hand and gauze before cutting to avoid blood splattering.
- Initiate feeding within the first hour of birth according to the mother's preferred and informed choices.

Infant Feeding Choices

Breastfeeding provides the infant with all required nutrients and immunological factors that help to protect against common infections. This protection is reduced when the child is given water or any other substance during exclusive breastfeeding. Mixed feeding, i.e. breast milk and formula feeds combined is the most hazardous form of infant feeding. Exclusive replacement feeding is the ideal option but it may not be affordable and feasible, where safe drinking water, fuel or clean utensils are scarce. In such scenario HIV infected women should be counseled during the antenatal period about infant feeding choices and to make an informed decision.

Where exclusive replacement feeding is AFASS—acceptable, feasible, affordable, sustainable and safe, avoidance of all breastfeeding is recommended. The mother who has chosen not to breastfeed must be able to prepare feeds hygienically and should be advised to use cup feeding and not bottle feeding. In case replacement feeding is not possible, exclusive breastfeeding for the first-six months of life with early cessation is recommended. The risks of HIV transmission especially if combined with ART may be less than 0.5 percent, if exclusive breastfeeding is done. If family support is not present, exclusive breast feeding may be difficult and the parent(s) may need consistent psychosocial support.

When the child reaches the age of six months or earlier, breastfeeding should be stopped within two weeks while ensuring the comfort level of both mother and infant. At the same time, good quality complimentary foods should be introduced, ensuring adequate amounts of energy proteins and micronutrients.

Sharandeep Kaur, Jagdish Chandra

BACKGROUND

The burden of HIV infection in India is huge with estimated adult HIV prevalence of 0.31 percent. According to 2009 data, approximately 23.9 lakh people are living with HIV/AIDS (PLHA) in India. The National AIDS Control Program Phase III (2007-2012) aims to halt and reverse the epidemic of HIV in India over next five years. The strategies to achieve this goal involve preventive measures as well as measures to improve care, support and treatment of people living with HIV/AIDS (PLHA). As the mortality rate is high in children living with HIV/AIDS (CLHA), hence their management is challenging.

Management of Children with HIV Infection

The management of CLHA involves a multidisciplinary approach with appropriate attention to growth, nutrition and immunization of child. It also includes treatment and prevention of opportunistic infections as well as antiretroviral therapy (ART).

PROPHYLACTIC THERAPY**Cotrimoxazole Prophylactic Therapy**

WHO recommends the use of Cotrimoxazole for prevention of *Pneumocystis jiroveci* infection in CLHA. Apart from *P. jiroveci*, CPT also provides protection against toxoplasma, malaria and other common bacterial infections. Cotrimoxazole prophylactic therapy (CPT) should be started in all infants born to HIV infected mothers starting at 4 to 6 weeks age or at first visit to the health care facility. It should be continued till HIV infection has been ruled out and the child is no longer exposed to HIV via breast milk.

In CLHA of 1 to 5 years age, CPT should be started if

- WHO clinical stage 2, 3 or 4 regardless of CD4 counts or

- If CD4 count <25 percent irrespective of WHO clinical stage.

For CLHA >5 years age, CPT should be started if

- WHO clinical stage 2, 3 or 4 if CD 4 count not available or
- WHO stage 3 or 4 irrespective of CD 4 count or
- CD 4 count <350/mm³ irrespective of WHO staging.

Dose

5 mg/kg/day.

Duration

Once started, CPT should be continued till 5 years age. After 5 years age, consider stopping, if CD 4 count >350 cells/mm³ on two occasions at least 3 months apart.

CPT should also be discontinued in HIV exposed infants when HIV infection has been excluded and the child is no longer exposed to HIV via breast milk.

Side Effects

Side effects are mild and include rash, myalgia, pruritus and GI upset. Severe side effects warranting discontinuation are uncommon and include severe anemia, pancytopenia, severe cutaneous reactions like Stevens-Johnson syndrome, hepatotoxicity or nephrotoxicity.

Contraindications

CPT should not be used in children with glucose 6-phosphate dehydrogenase deficiency or hypersensitivity to sulpha drugs.

Alternative Drug

Dapsone can be used in case of intolerance or severe side effects of CPT at 2 mg/kg/day.

Isoniazid Prophylactic Therapy (IPT)

Screening for TB is strongly recommended for all CLHA. WHO recommends three i's for decreasing morbidity and mortality of TB in CLHA.

- Establish *Intensified* TB case finding.
- Introduce *Isoniazid* preventive therapy
- Ensure TB *Infection* control in health care settings.

Regimen

WHO strongly recommends 6 months IPT for CLHA >1 year age who have no contact with a TB case and are unlikely to have active TB on symptom based screening. For infants with HIV, IPT is recommended for only those who have a contact with TB case and who are unlikely to have active TB.

Apart from above recommendations, 6 months IPT should also be given in CLHA after successful completion of treatment for TB.

Dose

INH is given at a dose of 10 mg/kg/day.

Side Effects

rash, nausea, vomiting and hepatotoxicity.

Other Prophylaxis

Antifungal prophylaxis with azoles has been recommended for adults with HIV living in cryptococcal endemic areas but no such recommendations have been made for children.

ANTIRETROVIRAL THERAPY

Antiretroviral therapy (ART) decreases the mortality in CLHA. Therefore early effective ART is recommended by WHO and NACO. It is important to realize that ART is not a cure for HIV infection, however it improves the long term outcome of CLHA.

Pre Art Work Up

The following work up is needed before a child is started on ART.

Clinical

- Weight, height, head circumference and other measures of growth
- Nutritional status, including assessment of dietary intake
- Developmental assessment
- Concomitant medical conditions (e.g. hepatitis B or C infection, TB, other coinfections or OIs)
- WHO clinical staging
- Details of drugs the child may be receiving, including co-trimoxazole therapy.

Laboratory

- Hemoglobin and complete blood counts
- Biochemical tests: Liver function tests (LFTs), kidney function tests (KFTs), blood glucose, serum electrolytes and if available serum lipids, amylase and lipase levels
- Pregnancy test in adolescent girls (especially those who are going to start on EFV based regimen).
- CD 4 counts and percentage
- Viral load if available.

PRE ART COUNSELING

Once started ART has to be continued lifelong. Hence, identification of primary care giver who understands the implications of ART (lifelong treatment, importance of adherence, side effects) is required. Identifying a secondary care giver who will take care of the child in the absence of primary care giver is also advised. Adequate counseling of caregiver regarding dose, duration, timing and side effects of drugs is mandatory before initiating ART. A 90 percent adherence is recommended for optimum outcome.

TIME OF INITIATION OF ART

NACO recommends ART in

- All infected children <24 months age.
- In children <18 months of age with presumptive clinical diagnosis of HIV.
- In 24 to 59 months age:
 - If WHO clinical stage 3 and 4 disease or
 - CD4 <25 percent or CD 4 count <750 cells/mm³ whichever is lower.
- For >60 months age:
 - If WHO clinical stage 3 and 4 disease or
 - CD4 count <350/mm³.

For CLHA with clinical stages 1 or 2 disease, ART should be started when CD 4 counts falls close to threshold value for initiation of ART for each age group as a drop below the threshold value is associated with higher mortality.

ART in Children with Tuberculosis Infection

- All infants with a diagnosis of TB (PTB or EPTB) should be started on ART
- All children with a diagnosis of EPTB except tubercular lymphadenopathy (TBLN) should be started on ART irrespective of CD4 counts.
- All children with a diagnosis of PTB or TBLN should be considered for ART as follows:
 - On the basis of CD4 counts
 - If CD4 measurements are not available, then children should be started on.

Presumptive Diagnosis of HIV

In HIV antibody positive cases <18 months age, where a confirmation of HIV infection is not possible because of

non-availability of virological testing, presumptive diagnosis of severe HIV infection can be made if he/she has positive HIV antibody test and has two of the following: severe pneumonia, severe sepsis or thrush. Other factors that support the diagnosis of severe HIV disease in an HIV seropositive infant include: recent HIV—related maternal death; or advanced HIV disease in the mother or if the patient has CD4 <20 percent. Such cases should be started on ART with family being informed about possibility of HIV infection. However, the confirmation of HIV infection should be done as soon as possible using age appropriate testing methods. ART should be stopped only when the diagnosis of HIV infection has been ruled out and the child is no longer exposed to infection via breastfeeding from an HIV infected mother. Presumptive diagnosis of HIV disease should not be used in children >18 months age as antibody testing establishes their HIV infection status.

Note

For resource poor settings where CD4 counts are not available, total leukocyte count should not be used as a substitute for CD4 counts. Determination of viral load is not considered a prerequisite to start ART. Defer ART until all acute infections have been treated.

ART DRUGS

ART drugs belong to one of the following categories:

- Entry inhibitors:
 - Chemokine coreceptor (CCR/CXCR) antagonist: Maraviroc
 - Fusion inhibitor: Enfuvirtide (T-20)
- Reverse transcriptase inhibitors:
 - Nucleoside reverse transcriptase inhibitors (NRTI/ NRTI): Zidovudine* (AZT), Stavudine* (d4T), Lamivudine* (3TC), Emtricitabine (FTC), Didanosine (ddl), Abacavir (ABC)
 - Nucleotide reverse transcriptase inhibitors (NtRTI): Tenofovir* (TDF)
- Non-nucleoside reverse transcriptase inhibitors (NNRTI): Nevirepine* (NVP), Efavirenz* (EFV)
- Integrase inhibitors: Raltegravir
- Protease inhibitors: Atazanavir (ATV), Ritonavir* (RTV), Lopinavir* (LPV), Saquinavir (SQV), Indinavir (IDV), Nelfinavir (NFV), Amprenavir (APV), Fosamprenavir (FPV), Tipranavir (TPV), Darunavir (DRV) (*Drugs available at NACO ART programmes for use in children).

MECHANISM OF ACTION

Life Cycle of HIV

After attachment to the glycoprotein receptors of cell, the virion enters the cell by fusing with the cell membrane. After entry into the cell, the viral RNA forms viral DNA

by the enzyme reverse transcriptase. The viral DNA integrates with host DNA with the help of enzyme integrase and the viral protein is formed by translation. The final step involves enzyme protease which helps in cleaving the protein, budding and maturation of the virion leading to lysis of cell and infection of a new cell with the released virion. Figure 1 depicts the life cycle of HIV and mechanism of action of ART drugs.

INDIVIDUAL DRUGS

NNRTI

Zidovudine (AZT)

AZT, a thymidine analog is the prototype NRTI. It is effective against HIV 1 and HIV 2. After phosphorylation in

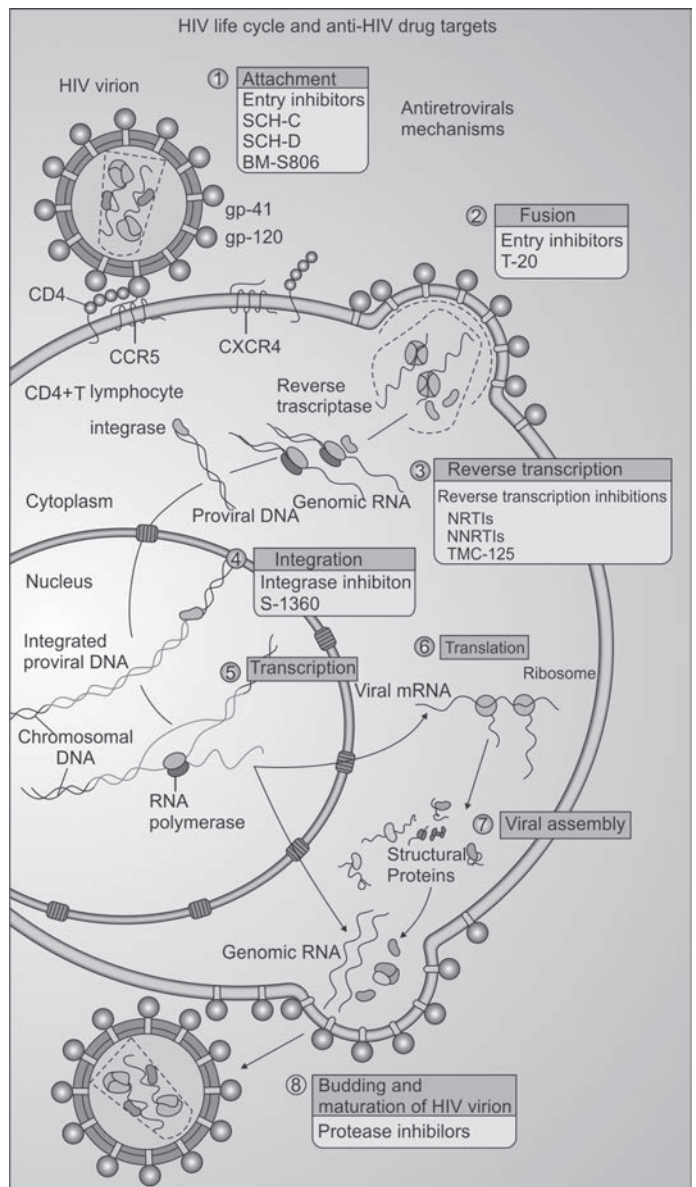

Fig. 1: Mechanism of antiretroviral drug action

the host cell, AZT selectively inhibits viral reverse transcriptase. Hence it prevents infection of new cells by HIV but has no effect on virus directed DNA that has already been integrated into the host chromosome. It also reduces the rate of vertical transmission from mother to child. It is orally absorbed with 65 percent bioavailability and is metabolized in liver. It can cross placenta and is also secreted in breast milk. Hence, it is used for PMTCT.

Side Effects

It is well tolerated by children. The toxicity is due to partial inhibition of cellular DNA polymerase. AZT can lead to anemia and neutropenia by causing bone marrow suppression. Hence hematological monitoring and close follow-up for Hb is advised for children on AZT based regimens (Hb tests to be done at 15 days, 1 month, 2 months, 3 months and six months). Although initial side effects are more common with AZT, it is preferred over other NRTI for long term use. In case of intolerance to AZT, it is substituted with either d4T or ABC, except in cases of lactic acidosis where ABC is preferred.

Dose

180- 240 mg/m²/dose twice daily with a maximum dose 300 mg twice daily.

Stavudine (d4T)

d4T is also a thymidine analog and is effective against both HIV 1 and HIV 2. It is well absorbed orally and is rapidly metabolized. It is used as an alternative to AZT in cases of anemia and neutropenia as it does not have hematological side effects and does not need hematological monitoring. d4T accumulates intracellularly and affects mitochondrial metabolism leading to mitochondrial toxicity, thereby causing side effects like lactic acidosis, peripheral neuropathy, hepatotoxicity and pancreatitis. As the toxicity occurs because of intracellular accumulation of drug and its metabolites, hence the toxicity is gradual and frequently irreversible. The incidence of side effects is less in children as they have higher clearance rate as compared to adults.

Dose

For children with weight <30 kg, the dose is 1 mg/kg/dose twice daily and for children with weight >30 kg, the dose is 30 mg/dose twice daily.

Lamivudine (3TC)

3TC is a deoxycytidine analogue and is a potent NRTI. It is the core component of dual NRTI backbone. It is effective against HIV 1, HIV 2 and Hep B. Point mutation in HIV reverse transcriptase and HBV DNA polymerase gives rise to rapid resistance to 3TC. Some 3TC resistant

mutants also become slow growing. It is absorbed orally and is mostly excreted unchanged in urine. The side effects associated with the use of 3TC are nausea, vomiting, rash and rarely hepatotoxicity.

Dose

2 mg/kg/dose twice daily for infants <30 days old. For >30 days old: 4 mg/kg/dose twice daily. For children with weight >50 kg the dose is 150 mg twice daily.

Abacavir (ABC)

Is an alternative NRTI in first line therapy. It is absorbed orally and it can be taken with food. Of all NRTI, ABC has the least effect on mitochondria and is the preferred substitute for AZT or d4T in children developing lactic acidosis. ABC is associated with fatal hypersensitivity reaction in 3 percent children. Hence, caregivers should be informed about this side effect prior to starting ABC. In children suspected to have hypersensitivity reaction, ABC should be stopped and should never be restarted. Other less severe side effects include nausea, malaise, headache and diarrhea.

NVP and EFV

NVP and EFV are the 2 NNRTI used for ART. NNRTI directly inhibit viral reverse transcriptase without the need for intracellular phosphorylation. Both act against HIV 1 only. NNRTI are potent inducers of hepatic cytochrome P450 and hence induce metabolism of other drugs as well as their own metabolism lead to many drug interactions.

Nevirepine (NVP)

Nevirepine (NVP) is the only NNRTI recommended for use in infants and is the component of all 3 drug FDC currently available. It is well absorbed orally and is extensively metabolized by liver. NVP should never be used alone except when it is given for prophylaxis. Rifampicin decreases the NVP concentration by 20 to 58 percent. For this reason and because of occurrence of hepatotoxicity with both drugs, Rifampicin and NVP are not used together. NVP is preferred in adolescent girls where EFV is contraindicated because of teratogenicity. The potentially life-threatening side effects associated with the use of NVP are hepatotoxicity and skin rash including Stevens Johnson syndrome. It has a higher incidence of rash as compared to other ART drugs.

To decrease the incidence of side effects associated with NVP use, it is given by introducing in small doses (Lead in Period) and gradually the dose is increased. During the lead in period, less dose is given for first 14 days of therapy that leads to decreased incidence of side effects. NVP being an enzyme inducer induces its own metabolism and hence leads to decrease of its own blood levels

after 14 days. Hence, the dose has to be increased after 14 days to achieve optimum effect. However, if the child is already on an EFV-based regimen, and should be put back on NVP, a lead-in dose of NVP is not required.

Dose

160 to 200 mg/m² to a maximum dose of 200 mg twice daily.

Efavirenz (EFV)

Efavirenz (EFV) is NNRTI and is used in CLHA with concomitant active TB. It is less well absorbed orally but has longer half life as compared to NVP. It is not currently recommended for children <3 years of age because of nonavailability of pharmacokinetic data and no consensus regarding dosage. Its bioavailability is increased with a fatty meal. The common side effects are rash, CNS toxicity and teratogenicity. Hence, it is contraindicated in psychiatric patients and adolescent females not using any contraception method. For decreasing CNS side effects, it is given as a bed time dose or 2 to 3 hours after food. The patient should be warned regarding restriction of risky activities during initial 2 to 4 weeks of therapy.

Dose

15 mg/kg/day.

Protease Inhibitors (PIs)

Protease inhibitors (PIs) viral replication by inhibiting the enzyme protease that helps in assembly of new viral particles. As they act at a late step of viral cycle, they are effective in both newly and chronically infected cells. Under their effect, HIV infected cells produce noninfectious viral progeny, hence prevent further infection. RTV is an exception because it is not used for its antiviral property. Rather it is used because of its inhibitory effect on hepatic metabolism and hence it boosts the effect of other PIs. The side effects of PIs include dyslipidemia, lipodystrophy, hepatotoxicity, hyperglycemia, coagulopathy, osteoporosis and vascular necrosis.

Lopinavir (LPV)

Lopinavir (LPV) is the most commonly used PI. It is effective against both HIV 1 and HIV 2. It is used as boosted LPV with RTV (LPV/r). A high fat meal increases its absorption. Hence, it should be given with food. The common side effects are pain abdomen, GI upset and hepatotoxicity. Monitoring of hepatic function is required in children taking LPV especially in children with pre existing liver disease.

ART Regimens

Fixed drug combinations (FDCs) are used for ART to improve adherence. FDC tablets supplied under the national initiative cover children with >5 kg body weight.

For children <5 kg body weight, ARVs have to be in the form of syrups or suspension. It is recommended not to cut adult drugs for administration to children as this may result in inappropriate dosing.

Current ART Regimens for Use in Children Under NACO

The standard first-line regimen used for ART is triple drug therapy (2NRTI + 1 NNRTI). The commonly used NRTI are Zidovudine (AZT), Stavudine (d4T), Lamivudine (3TC) and Abacavir (ABC). The commonly used NNRTI are Efavirenz (EFV) and Nevirepine (NVP).

The first-line regimens for use in children have been labeled as PI, PIa, PII, PIIa, PIII, PIIIa, PIIIb, PIV and P IV a (Table 1).

Regimen PV is the pediatric second-line ART regimen recommended by NACO.

CHOICE OF FIRST LINE ANTIRETROVIRAL THERAPY

- For children not exposed to NNRTI, AZT+ 3TC+NVP is the preferred regimen
- For children exposed to maternal or infant NVP or other NNRTIs used for maternal treatment or PMTCT, the regimen is AZT+3TC+LPV/r as there is a risk of viral resistance to NVP in those exposed to NVP.
- If exposure to ARV is unknown, the regimen is 2NRTI+1 NNRTI.

Special Circumstances

- Anemia/neutropenia: If CLHA has hemoglobin <9.0 gm/dL or neutrophil count <500cells/mm³, avoid AZT and replace it with d4T.
- In children with concomitant active TB, NVP should be avoided and EFV should be used. EFV should not be used in children <3 years age/weight <10 kg and adolescent girls due to its teratogenicity in first trimester.
- Avoid NVP in adolescent girls with CD4 counts >250 cells/mm³ as there is risk of hepatotoxicity.
- For adolescents more than 12 years of age with hepatitis B, the preferred regimen is TDF+ FTC or 3TC+ NNRTI.
- Triple NRTI regimen (AZT/d4T+3TC+ABC) is used in cases of infant and children <3 years of age with active TB and pregnant adolescent girls with CD4 counts >250 cells/mm³.

For most ART drugs, tablets and capsules are available in sufficiently low doses for accurate dosing in children but some drugs do not have solid formulations in doses appropriate for pediatric use.

Initiation of ART in children may lead to rapid weight gain of child, hence the child must be weighed at each visit and the dosage of ART drugs should be changed accordingly to avoid under dosing.

Table 1: Current first line ART regimen for children

<i>National paediatric ART regimen</i>	<i>Type of regimen</i>	<i>Regimen</i>	<i>Remarks</i>
Regimen PI	First-line regimen	Zidovudine+Lamivudine + Nevirapine	Preferred pediatric regimen for starting ART
Regimen PI(a)		Stavudine + Lamivudine + Nevirapine	This regimen is for children starting ART who have Hb ≤ 9 g/dl
Regimen PII		Zidovudine+Lamivudine + Efavirenz	Preferred for children on antituberculosis treatment; Hb >9 g/dL and age >3 yr and weight >10 kg
Regimen PII(a)		Stavudine + Lamivudine + Efavirenz	For children on antituberculosis treatment; Hb ≤ 9 g/dl and age >3 yr and weight >10 kg
Regimen PIII	Alternative first-line regimen	Abacavir + Lamivudine + Nevirapine	For patients not tolerating AZT or d4T on a NVP-based regimen
Regimen PIII(a)		Abacavir + Lamivudine + Efavirenz	For patients not tolerating AZT or d4T on a EFV-based regimen
Regimen PIII(b)		Abacavir + Lamivudine + Lopinavir/Ritonavir	For patients not tolerating AZT or d4T on a LPV/r-based regimen e.g. infants started on LPV/r due to prior exposure to PPTCT regimens containing NNRTI (NVP or EFV).
Regimen PIV		Zidovudine + Lamivudine + Lopinavir/Ritonavir	For patients not tolerating both NVP and EFV, and Hb >9 g/dl
Regimen PIV(a)		Stavudine + Lamivudine + Lopinavir/Ritonavir	For patients not tolerating both NVP and EFV and Hb ≤ 9 g/dl

Side Effects of Antiretroviral Therapy (ART)

Antiretroviral therapy ART drugs have side effects that vary from mild to severe. The following grading system has been proposed for assessing the side effects of ART drugs:

Grade 1 (mild): Symptoms are mild and can be treated with simple drugs, e.g. the use of antihistaminics for rash. Grade 1 reactions do not require discontinuation of therapy.

Grade 2 (moderate): Lead to mild to moderate limitation of activity and require no/moderate medical intervention. ART drugs should be continued but if the side effects persist or if the child does not improve on symptomatic treatment, consider single drug substitution.

Grade 3 (severe): Lead to significant limitation of activity and sometimes hospitalization is required. The offending drug should be substituted without discontinuing ART.

Grade 4 (life-threatening): Lead to extreme limitation of activity and require complete stoppage of ART drugs. ART should be started only after the acute event has been managed and the regimen should be changed.

The common side effects seen with ART drugs are following:

- **Hematological:** Anemia and neutropenia are common side effects and are seen most commonly with AZT. This has an important implication for children residing in malaria endemic areas and also because children

with HIV are malnourished and anemia might be present at the time of initiation of ART.

- **Mitochondrial toxicity:** Because of their effect on mitochondrial metabolism, ART drugs can cause mitochondrial toxicity. The common side effects are lactic acidosis, pancreatitis, hepatotoxicity and peripheral neuropathy. d4T and ddI are the commonly offending drugs.
- **Lipodystrophy:** Abnormalities include fat maldistribution and body habitus changes, hyperlipidemia, hyperglycemia, insulin resistance, diabetes mellitus, osteopenia, osteoporosis and osteonecrosis. These are most commonly seen with d4T.
- **Allergic reactions:** Including skin rashes and hypersensitivity reactions are more common seen with the NNRTI drugs most common with NVP.

Table 2 depicts the common side effects of ART drugs and the drugs that can be used for substituting the ART drug.

Substitution and Switch

“Substitution” is “replacement of a single ARV drug for reasons of toxicity, drug-drug interactions, or intolerance” (usually within the same class) whereas “switch” refers to “replacement of the entire first line regimen in cases of treatment failure” (identified by clinical and/or immunological and/or virological monitoring).

Follow-up of Children on Antiretroviral Therapy (ART)

Children on ART should be followed up once every month for initial 6 months. In patients on NVP, the first follow-up should be at 15 days (the 'lead-in period') followed by the monthly schedule.

Clinical evaluation at every visit should include evaluation for efficacy of treatment which includes clinical improvement including weight gain. Clinical staging using the WHO T staging should be performed. T staging uses the same WHO clinical staging used in initial evaluation and takes into account any new events. Opportunistic infections, if any should be detected and managed. A clinical review for TB should also be done at every visit. Patient should also be assessed for IRIS. Monitoring for adverse drug reaction and counseling for adherence should be an integral part of clinical evaluation.

Treatment Failure and Second Line Antiretroviral Therapy (ART)

Second line drugs are used in case of clinical, immunological or viral failure. The drugs used for second line therapy are less effective, expensive and have more side effects. Hence, before starting a child on second line therapy, it is mandatory to ensure that adequate trial has been given to first line drugs (at least 24 weeks); adherence has been maintained (at least 90%) and all acute opportunistic infections have been treated and immune reconstitution inflammatory syndrome (IRIS) has been ruled out.

Clinical Failure

Refers to progressive neuro-developmental deterioration and/or growth failure despite adequate nutritional support and/or development of new OI or malignancy in an

Table 2: Common side effects/toxicity of antiretroviral drugs

<i>First-line ARV drug^a</i>	<i>Most frequent significant toxicity for the ARV drug</i>	<i>Suggested first-line ARV drug substitution</i>
Zidovudine	Severe anemia ^a or neutropenia ^b	Stavudine or abacavir
	Lactic acidosis	Abacavir
	Severe gastrointestinal intolerance ^c	Stavudine or abacavir
Stavudine	Lactic acidosis	Abacavir ^d
	Peripheral neuropathy	
	Pancreatitis	
	Lipoatrophy/metabolic syndrome ^e	Zidavudine or abacavir
Niverapine	Acute symptomatic hepatitis ^f	Efavirenz ^g
	Hypersensitivity reaction	Preferred substitution by either:
		• A third NRTI (disadvantage, may be less potent) or
	Severe or life-threatening rash (Stevens-Johnson syndrome) ^h	• PI (disadvantage, premature start of 2nd line ARV drug) ⁱ
Efavirenz	Persistent and severe central nervous system toxicity ^j	
	Potential teratogenicity (adolescent girl in 1st trimester pregnancy or of childbearing potential not receiving adequate contraception)	Niverapine
Abacavir	Hypersensitivity reaction	Zidovudine

a. Exclude malaria in areas where malaria is prevalent.

b. Defined as severe hematological abnormality that can be life-threatening and that is refractory to supportive therapy.

c. Defined as severe, refractory gastrointestinal intolerance that prevents ingestion of ARV drug regimen (e.g. persistent nausea and vomiting).

d. Abacavir is preferred in this situation as it is the least likely of the NRTIs to cause lactic acidosis; however, where abacavir is not available, zidovudine may be used.

e. Substitution of Stavudine may not reverse lipoatrophy, but may prevent further progression of the condition. In children, Abacavir or Zidovudine can be considered as alternatives.

f. Symptomatic Niverapine-associated hepatic toxicity is very rare in HIV-infected children prior to adolescence.

g. EFV is not currently recommended for children <3 years of age or <10 kg, and should not be given to postpubertal adolescent girls who are either in 1st trimester of pregnancy or are sexually active and not using adequate contraception.

h. Severe rash is defined as extensive rash with desquamation, angioedema, or serum sickness-like reaction; or a rash with constitutional findings such as fever, oral lesions, blistering, facial edema, conjunctivitis; Stevens-Johnson syndrome can be life-threatening. In most cases of nonlife-threatening Niverapine -associated rash, Efavirenz may be introduced with caution and monitored for adverse events. For life-threatening rash, most clinicians would not substitute Efavirenz due to the potential for NNRTI-class specific toxicity.

i. The premature introduction of the PI class of drugs in first-line regimens limits the choice of drugs in the event of treatment failure

j. Defined as severe central nervous system toxicity such as persistent hallucinations or psychosis

adherent child on ART. For CLHA with pulmonary or lymph node TB or severe recurrent pneumonia (all are stage 3 conditions), a trial of appropriate ATT and antibacterial therapy should be given before switching a child on to second line therapy.

Immunological Failure

Is defined as a drop in CD4 counts after initial immune recovery following ART initiation, to values at or below the age related CD4 cut offs given below or a failure of the CD4 count to rise above these threshold values. Recognition of treatment failure on the basis of immunological values relies on comparison with previous CD4 values, and underscores the need for CD4 measurement at the start of ART. At least 2 CD4 counts are required before declaring immunological failure.

In a fully adherent child ART failure is considered if:

- In 2 years to <5 years old child, the CD4 count is <200cells/mm³ or <10 percent
- In >5 years old child, if CD4 <100cells/mm³.

For children <2 years old, specialist advice should be sought before labeling immunological failure.

Virological Failure

Is recognized as persistent viral load above 5000 copies/ml after 24 weeks treatment in a fully adherent child.

At present, NACO does not recommend routine determination of viral loads in children on ART.

Note

If in a child the CD4 count fall but remain above the threshold level and there are no new clinical event, a switch of regimen is not recommended.

New or recurrent WHO clinical stage 4 conditions may warrant a switch in treatment regimen, although if the CD4 value remains above the age-related thresholds, it may be acceptable to delay switching.

Choice of Second Line Drugs

The following guidelines have been proposed for second line ART in children:

NACO regimen P 5 is second line ART in children. This includes:

ABC+ 3TC+ ddi+LPV/r

- After failure on a first-line NNRTI-based regimen, a boosted PI plus 2 NRTIs are recommended for second-line ART.

LPV/r is the preferred boosted PI for a second-line ART regimen:

- After failure on a first-line regimen of AZT or d4T + 3TC, ABC + 3TC is the preferred NRTI backbone option for second-line ART; ABC + ddi is an alternative.
- After failure on a first-line regimen of ABC + 3TC, AZT + 3TC is the preferred NRTI backbone option for second-line ART; AZT + ddi is an alternative.

- Treatment failure on an alternative triple NRTI regimen can be managed by using drugs from NNRTIs and PIs. The PI component remains essential in constructing a second-line regimen.
- If a child is on a regimen of LPV/r, and also requires ATT, add RTV (LPV/r+r) to a 1:1 ratio of LPV: RTV (superboosting) to achieve full therapeutic dose of LPV.
- If a PI was used as a substitute for a first-line NNRTI drug because of severe toxicity, should the PI fail, it is not considered safe to reintroduce the NNRTI class of drugs.
- As there is cross resistance between AZT and d4T, substituting one with the other is not recommended and both should be replaced with ABC.

Wherever possible, at least one new class of drugs should be used in a second-line regimen.

HIV and TB Coinfection

HIV infection increases the susceptibility to infection with *M. tuberculosis*, the risk of rapid progression to TB disease, and reactivation of disease in older children with latent TB. The comanagement of HIV and TB is complicated by the presence on drug interaction between ATT drugs and ART drugs. WHO proposed the following guidelines for any child with TB and HIV coinfection:

- Any child with active TB disease should begin TB treatment immediately, and ART should be started as soon as tolerated in the first 2 to 8 weeks of TB therapy, irrespective of the CD 4 counts or clinical stage.
- For children already on ART drugs, replace NVP with EFV in children >3 years age.
- For children <3 years age and not exposed to NNRTI, the preferred regimen is 2 NRTI+ NVP or 3NRTI.
- If child is on 2NRTI + NVP and substitution with EFV is not possible, ensure NVP is dosed at maximum dose of 200 mg/m² per dose twice daily.
- For those coinfecting with TB/HIV whose anti-TB treatment includes rifampicin, the dosage of RTV in the LPV/r regimen can be increased to a ratio of 1:1 in order to achieve adequate LPV exposure (superboosting; LPV/r+r).

Note: ART in children should be given using NACO weight band guidelines.

Viral Encephalitis Including Japanese Encephalitis

Milind M Gore, KP Kushwaha

INTRODUCTION

Central nervous system (CNS) infections due to its preferred position and protection are rare, however, when any CNS abnormality happens it manifests as a very severe disease. In addition, residual damage due to loss of nervous tissue also leads to disabilities at various physical and mental levels. There are numerous medical conditions which may produce an encephalopathic illness; from traumatic to metabolic to immunopathological causes, which may mimic viral encephalitis, Encephalitis refers to an acute, usually diffuse, inflammatory process affecting the brain. While meningitis is primarily an infection of the meninges, a combined meningoencephalitis may also occur. An infection by a virus is the most common and important cause of encephalitis, although other organisms may sometimes cause an encephalitis. A number of metabolic conditions including liver and renal failure and diabetic complications may also cause confusion in diagnosis. (Kennedy, 2004). The time course of the viral encephalitis can be acute, subacute or chronic. Pathologically, there are encephalitis with direct viral entry into the CNS in which brain parenchyma exhibits neuronal damaging and viral antigens. In postinfectious autoimmune encephalitis is associated with systemic viral infections with brain tissue presenting perivascular aggregation of immune cells and myelin damaging (Domigues, 2009).

In order to capture all cases of encephalitis, WHO introduced a term acute encephalitis syndrome (AES). AES is defined as “a disease with acute onset of fever and a change in mental status (including symptoms such as confusion, disorientation, coma, or inability to talk) and/or new onset of seizures (excluding simple febrile seizures) in a person of any age at any time of year. (Soloman et al 2008). After enrolling the AES cases, differential diagnosis should therefore include viral encephalitides (e.g. conditions caused by arbo viruses and herpes viruses) and

infections that involve the central nervous system (e.g. bacterial meningitis, tuberculosis and cerebral malaria) (Dhillon and Raina, 2008).

Acute Encephalitis Syndrome in India

Average state-wise yearly incidence of AES in India for last seven years shows that Uttar Pradesh has the highest cases of AES followed by Assam and Bihar (<http://nvbdcp.gov.in/je-cd.html>) (Fig. 1). It should be noted here that a many of these reports are based on cases admitted in the tertiary government hospitals and thus patients not reaching the hospitals or taking treatment in private nursing homes are not listed. As diagnosis of etiological agent does not alter the treatment modalities no serious attempt is made to diagnose the viral agent. Monthly incidence of AES in various states indicates that in most states AES cases occur during rainy season (Fig. 2). In southern states like Andhra Pradesh and Tamil Nadu, cases can be seen in months of November to January due to south east monsoon in that region, while in northern India there is only one peak during August to October.

A detailed analysis of AES cases from 2008 to 2010 in Gorakhpur and Basti revealed that AES cases have been continuously occurring in eastern Uttar Pradesh since 2005. Most affected districts are Gorakhpur, Kushinagar, Mahrajganj and Deoria. Cases occur throughout the year with highest number of cases during July-October. (Figs 3 and 4.) Mean case fatality rate is 16.77 percent (Range 1.4 to 68%). Age distribution of cases over last three years in Gorakhpur region has indicated that most of the cases (48.4%) are in the pediatric age group and mainly in the age group of 1-10. (Fig. 5) Based on the projected population estimates of 2010 the average incidence of AES cases is 14.7 cases/100,000 population in four most affected districts while it is 6.34 cases/100,000 population in less endemic districts of Basti, Sant Kabir Nagar and Siddharth

Fig. 1: Average incidence of AES cases in different states in India

Fig. 2: Monthly distribution of AES cases in different states in India since 2006

Nagar. In Assam however as the rainy season starts earlier, cases of AES occur during April-September with peak activity during months of July and August. Most cases are encountered in age group >15 (65.9%) and cases in the pediatric age group are only 34.2 percent (Fig. 48.6).

Reporting of etiological diagnosis of AES cases depends on the quality of health information systems and the ability to clinically and serologically diagnose the disease. Diagnosis of bacterial and parasitic etiologies of AES is comparatively easier and is carried out on the basis of various clinical, pathological tests. In addition, various low cost diagnostic tests are also available. These cases mainly occur as sporadic cases and are treatable with drugs. In Gorakhpur about 5 percent of AES cases are diagnosed as

having bacterial meningitis while another 4 percent are of tubercular meningitis (NIV data).

Diagnosis of viral meningoencephalitis is difficult and requires elaborate laboratory facilities and thus largely goes undiagnosed. In India, major sporadic viral encephalitis cases are thought to be due to measles and herpes viruses. In addition, limited localized outbreaks of Chandipura, Nipah viruses have been reported by NIV (Gurav et al 2010, Chadha et al 2005, 2006, Rao et al 2004). Recently WN virus encephalitis cases have been reported from Assam (Khan et al 2011). In a prospective study in Delhi India during 2004-05 it was shown that measles and mumps encephalitis constitutes about 7 percent and 10 percent of the viral encephalitis cases. (Karmarkar et al

Fig. 3: Monthly distributions of AES cases in Eastern Uttar Pradesh (cases admitted in BRD Medical College, Gorakhpur during 2007-2010)

Fig. 4: Average distribution of AES cases in various districts on eastern UP between 2007 and 2010

2008). In another study in Mumbai, India 3.3 percent of the hospital admitted cases of measles showed CNS manifestations. (Raote and Bhawe, 1992). Measles encephalopathy was diagnosed in 5 percent of AES cases. (Kumar et al 1990). In a study from Aligarh as many as 21 percent cases were diagnosed as measles encephalitis (Beig et al 2010). In Vidarbha, Telangana and few districts of Gujarat Chandipura outbreaks also occur (Gurav et al 2010, Rao et al 2004, Chadha et al 2005). Sero-survey in Warangal district has shown that by the age of 15 years >70 of the population has neutralizing antibodies against CHPV (Dr B.V. Tandale, NIV personal communication).

Another major agent that is emerging in causation of viral encephalitis/meningoencephalitis is enterovirus. NIV reported isolation of enterovirus 76 from CSF as one of the agents causing encephalitis in eastern Uttar Pradesh. (Sapkal et al 2009) Subsequent years although the isolations and detection in the CSF has decreased to about 2 percent, detection of enteroviruses in rectal swab samples has been continuing in about 30 percent of the cases. Various enteroviruses, e.g. Coxsackie B3, A11, A22; ECHO 9, ECHO 30, EV 79/89, have been detected in these samples from Gorakhpur and surrounding area. It should be noted that the same areas also have the highest rates

Fig. 5: Average age distribution of AES cases in eastern UP

of acute flaccid paralysis cases reporting every year. This area is however free from wild type polio virus. However, about 30 percent of the stool samples show presence of non polio enteroviruses. (<http://www.npsindia.org/bulletin.pdf>). In addition, a few studies have also reported detection of enteroviruses as one of the major causes of encephalitis. (Kumar et al 1990, Karmarkar et al 2008, Beig et al 2010). Recently, EV 75 has been detected from the CSF of AES cases from Karanataka (Lewthwaite et al 2010).

In South east Asia also enterovirus encephalitis is occurring as a regular feature. Taiwan, Thailand, Indonesia, Philippines have been reporting regular outbreaks of mainly enterovirus 71. Circulation of EV 71 as a causative agent of hand foot and mouth disease and myocarditis has also been reported regularly worldwide (Le et al 2010, Ooi et al 2010, Chen et al 2010, MMWR 2010).

Japanese Encephalitis

Japanese encephalitis (JE) is a vector-borne viral disease that occurs in South Asia, Southeast Asia, East Asia, and the Pacific (Solomon, 2006). An estimated 3 billion persons live in countries where the JE virus is endemic (UN Report, 2005) and the annual incidence of the disease is 30,000–50,000 cases (Solomon, 2006). Nearly half of the human population currently lives in countries where JEV occurs. The annual number of human deaths is 10,000–15,000, and the estimated global impact from JE in 2002 was 709,000 disability-adjusted life years (DALYs) (Solomon, 2006; WHO Report, 2008). The disease can cause irreversible neurologic damage. The JE virus (JEV) is mainly transmitted by the mosquito *Culex tritaeniorhynchus*, which prefers to breed in irrigated rice paddies. This mosquito species and members of the *Cx.gelidus complex* are zoophilic. Wading ardeid water birds (e.g. herons and

Fig. 6: Average age distribution of AES cases in Assam

egrets) serve as virus reservoirs but the virus regularly spills over into pigs, members of the family of equidae (e.g., horses and donkeys) and humans. Because infected pigs act as amplifying hosts, domestic pig rearing is an important risk factor in the transmission to humans. JE prevalence has been shown in these animals mainly by isolations and also by seroconversion. In India also, many studies have shown the dominance of *Culex tritaeniorhynchus* as a major vector. In Nepal sero-prevalence of JE in pigs, ducks, and horses was 48.11 percent, 26.79 percent, and 50.0 percent, respectively (Pant, 2006). A study in Gorakhpur area also gave similar figures in 2008 (NIV data). In Australia flying foxes have also been thought to be involved (Van den et al 2009).

Diagnosis

Diagnosis of JE is mainly done by IgM anti JEV antibody detection mainly in CSF of patients. In endemic region and during outbreaks serum IgM anti JE antibody can be taken as confirmed diagnosis. In pre ELISA days four-fold rise in Hemagglutination inhibiting (HI) antibodies against JE or four fold decrease in HI titer after 2 mercaptoethanol treatment was the only way of diagnosing a case. In recent years, availability of various good quality IgM capture ELISA kits have made it possible to quickly diagnose JE case. Sensitivity and the specificity of the various kits are comparable with minor differences (Lewthwaite et al 2010A). Use of monoclonal antibody based conjugate to detect the captured virus has also contributed to ease of operation of test. Many kits have now replaced mouse brain antigen source to tissue culture derived antigen increasing further the sensitivity of the test. In addition to this, detection of virus genome in CSF by reverse transcriptase polymerase chain reaction (RT-PCR) and quantitative PCR have also become available. This has

enabled to diagnose a JE case in the first three to five days (Swami et al 2008 Sapkal et al 2007). Test based on reverse transcription loop-mediated isothermal amplification (LAMP) has been developed (Chen et al 2010). Virus isolation from brain, CSF and peripheral blood leukocytes has also been used. (Sapkal et al 2007). In India, NVB-DCP has contributed immensely in increased surveillance network, establishment of diagnostic facilities at various medical colleges and hospitals, and regular supply of JE diagnostic kits made by NIV has made substantial gains in understanding the situation of JE encephalitis.

JE Outbreaks

JE is associated with rainfall and rice cultivation which are major mosquitogenic conditions. Thus, depending upon the rainfall pattern seasonality of JE varies. In India, since 2006 massive efforts are being made to understand the prevalence of JE amongst the AES cases. Major regional hospitals, ICMR laboratories and WHO surveillance network have contributed immensely in understanding the JE encephalitis situation in the country. Following data has been compiled from laboratories of RMRC Dibrugarh, NIV Gorakhpur Unit, Encephalitis group NIV Pune and NIV Bangalore Unit. NIV Pune and Bangalore Unit and RMRC Dibrugarh undertake diagnosis of JE for referred AES cases, while NIV Gorakhpur Unit carries diagnosis of JE for cases admitted in BRD Medical College, Gorakhpur respectively.

Despite the increasing attempts to centralize the case listing mechanisms, comprehensive data is still not available from most of the states. However, understanding of percentage positivity in referred samples gives an idea about the extent of the problem of JE in various states. Thus, about 3 to 6 percent of the cases from various districts of Maharashtra are JE IgM positive. Samples from

Rourkela in Odisha have also shown the JE positivity in -7.5 percent of cases during 2008 to 2010. Recent studies under the WHO surveillance program undertaken in selected center have given that about 10 to 20 percent of the total AES cases are JE in last few years. In Assam and other north eastern states JE positivity has been consistently high.

Data from Assam and Gorakhpur show a very divergent scenario of JE in India. In Gorakhpur JE constitutes 8 to 14 percent of the total AES cases. As the number of AES cases are very large actual number of JE cases are 176, 375 and 417 in year 2008, 09 and 2010. Maximum number of cases of JE occur in the age group 1 to 10 years. During 2008 no adult case of JE was detected, however during 2009 and 2010 31.8 percent of the JE cases are >15 year of age (Fig. 7). JE cases in UP occur during rainy season with peak activity in the months of August –October (Fig. 8).

Fig. 7: Average age distribution of AES cases in eastern UP

Fig. 8: Monthly distributions of JE cases in Eastern Uttar Pradesh (cases admitted in BRD Medical College, Gorakhpur during 2008-2010)

Fig. 9: Monthly distributions of JE cases in Assam during 2008-2010

Fig. 10: Average age distribution of JE cases in Assam

Data from Assam however shows that the case positivity rate in Assam for JE is substantially and consistently higher. 47.7 percent, 36.7 percent and 33.3 percent during 2008, 09 and 2010, respectively (Fig. 9). As in the case of AES seasonality of JE also peaks during July Aug because of the early rains in north east. Another divergent feature of this region is the age distribution of JE cases. Majority of the JE cases occur in age >15 years (68.5%) (Fig. 10). Reasons for this deviation in an area where JE activity has been present for a very long time is intriguing.

In rest of the country as in case of AES, the pattern is associated with rainy season. In Andhra Pradesh during summer's incidence of AES is without JE component as many Chandipura encephalitis cases are also encountered (Fig. 11).

JE in South Asia and South East Asia

In many countries in South and South East Asia, JE is endemic. Surveillance of JE has improved and listing of cases of AES and diagnosis of JE has substantially improved the actual enumeration of JE cases. Seropositivity of JE on an average is in tandem of what is seen in India. In Nepal, and northern India, large outbreaks occur in the summer/rainy months; in tropical areas of southern Vietnam, southern Thailand, Indonesia, Malaysia, the Philippines, and Sri Lanka, cases occur more sporadically and peaks are usually observed during the rainy season (Vaughn and Hoke, 1992). In Nepal a recent study shows 18 percent of AES cases to be JE positive (Singh et al 2009), while in 2005 a detailed study gave an estimate of about 55.3 percent (Saxena et al 2009). A study carried out during 2004 to 2005 has given percent JE positivity as 32 percent. (Weirzba et al 2008) This was also a fall out of a situation in Gorakhpur area where a very large epidemic of JE occurred with JE seropositivity of about 30 percent in more than 8000 cases. (NVBDCP) Various estimates of the disease burden have been reported. In neighboring Bangladesh, JE contributed only 4 percent of the AES cases during 2003 to 2005. It is possible that majority of the nonJE cases are due to enteroviruses (Hossain et al 2010).

In countries of South East Asia JE cases occur on regular seasonal basis. In Vietnam about 26 percent cases were due to JE while 9.3 percent were due to enteroviruses. (Le et al 2010). In Thailand, JE remains an important cause with 15 percent cases showing JE positivity in Bangkok hospitals. In Southern Thailand, the JE etiology was at a higher rate (26%) (Olsen et al 2010).

Fig. 11: Monthly distribution of JE cases in different states in India since 2006

In the absence of registering each case and providing diagnosis population based studies will always have bias. In Nepal study, it has been calculated to be 2.1/100,000 population. In another study, the rate was about 7.2 to 8.2/100,000 of children aged less than 10 years of age while it was 0.4/100,000 children with age >10 (Kari et al 2006) or even up to 24.1/100,000 (Weirzba et al 2008). In South India, a study showed the same as to be 15/10,000 children between 5 to 9 years (Gajanan et al 1995). Other studies in South East Asia also indicate the similar trends. In Gorakhpur region the average rate is 1.57/100,000 population in highly endemic four districts of Gorakhpur division while Basti division has the rate of 0.73/100,000 population.

Mortality due to JE has been estimated to be between 20 and 30 percent. In earlier studies it has been estimated to be about 37 percent (Kari et al 2006; Kumar et al 1990), 42 percent (Dhillon and Raina, 2008) while in recent studies it is about 20 percent (I.). Since last two years mortality in confirmed JE cases in Gorakhpur area has been seen to be 20 to 23 percent (NIV Data). In 2010 the mortality was reduced to 17.99 percent.

Molecular Epidemiology

Genetic studies suggest that JEV originated from an ancestral virus in the area of the Malay archipelago. The virus evolved, probably several thousand years ago into different genotypes (I–IV) and spread across Asia (Solomon et al 2003). The history of the clinical recognition and recording of JE dates to the 19th century. JE appeared as recurring encephalitis outbreaks in the summer season. The first clinical case of JE was recorded in 1871 in Japan. Half a century later, also in Japan, a large JE outbreak involving >6,000 cases was documented. Subsequent outbreaks occurred in 1927, 1934, and 1935. In 1924, an agent from human brain tissue was isolated; 10

years later, it was proven to be JEV by transfection into monkey brains. The role of *Cx. tritaeniorhynchus* as a vector and the involvement of wading ardeids and pigs as reservoir hosts were demonstrated in 1938 (Tsai, 1990). Extensive sequencing studies carried out throughout the region has resulted in identifying four genotypes of JE virus that are circulating. Until the early 1990s, only genotype-3 JE virus was identified in Japan, then, the genotype shifted to type-1 countrywide. In China, numerous genotype I JEV strains have been isolated from JE patients, mosquitoes and pigs while genotype III strains remain present in the circulation also. (Liu et al 2011, Wang et al 2010) In Japan, Genotype I was also isolated from horse (Shimajima et al 2011). In a comprehensive study in JEV isolates during 1983-2005 in South Korea, it was observed that Genotype 3 strains were predominant in Korea before 1993, when genotype 1 strain K93A07 was first isolated. The two genotypes were detected simultaneously in 1994 but since then, only genotype 1 has been isolated in South Korea (Yun et al 2010). Based on molecular epidemiological study of JEV in Vietnam, China and Japan, 8 subgroups of genotype 1 JEVs are circulating in East Asia and, at least, 4 of these subgroups are chronologically related and frequently introduced to Japan through China. Possibly, this subgroup distribution is due to bird migration and/or infected mosquitoes which carry viruses for long distances. While in Japan, a small population of genotype 1 is circulating locally. (Tang et al 2009; Morita, 2009; Fan et al 2010). Between 1935 and the 1990s, one of the Korean isolates fell into GII, demonstrating that GII has been circulating for at least 19 years longer than previously thought. (Schuh et al 2010) In India, all the strains that were isolated by various workers since 1956 were of genotype III. NIV has detected and isolated genotype I strains during outbreak of JE in Gorakhpur area (Fulmali et al 2011) (Fig. 12). A novel mutation S227T was detected

Fig. 12: Phylogenetic tree using a 1381 nt Japanese encephalitis virus envelope sequence directly amplified from CSF's collected in the acute phase of illness from hospitalized AES patients during September – November 2009. Phylogenetic analysis was performed by using nucleotide alignments, the maximum composite likelihood estimation algorithm (for the calculation of pairwise distances), and the neighbor-joining method (for tree reconstruction), as implemented in MEGA software (15). The tree was rooted within the Japanese encephalitis serogroup by using Murray valley virus (GenBank accession No. AF161266). The robustness of branching patterns was tested by 1,000 bootstrap pseudo replications. Each strain is abbreviated with accession number, strain name followed by country of origin and year of isolation. Bootstrap values are indicated above the major branch; 43 taxa comprised the ingroup, and all taxa were rooted with Murray valley encephalitis virus

corresponding to the loop region of domain II, E gene of JEV in comparison to Indian and other isolates from different parts of the world. (Pujhari et al 2010) The introduction of genotype I appears to be recent as even during the RTPCR analysis of CSFs in 2008 did not yield genotype I.

There are 10 fold differences in neutralization by antiserum against Beijing I strain that is used as vaccine in Japan (Nerome et al 2007). In Thailand JE strains from pigs and mosquitoes in 2003 to 2005 belonged to genotype I, which shows a switch from genotype III incidence that started during the 1980s. (Nitatpattana et al 2008) G I of JEV was introduced in China around 1979 and that JEV strains belonging to genotypes 1 and 3 circulate in China. (Wang et al 2007) In India, they are mainly G3, (Saxena et al 2009; Vrati, 2000, Sapkal et al 2007). Analysis using envelope, NS1, NS3, and NS5 genes revealed extensive divergence between the two Indian strains included (Uchil and Satchidanandam, 2008). Our studies on comparison of neutralizability of various strains it was observed that antisera raised against SA-14-14-2 vaccine virus could neutralize Genotype I viruses equally efficiently in comparison to genotype II strain isolated from India (Sapkal GN personal communication).

Clinical Course

Various clinical studies have documented features of clinical disease and the course of illness of JE. Symptomatic JEV infection manifests with nonspecific febrile illness, aseptic meningitis or encephalitis. Encephalitis manifests with altered sensorium, seizures and focal neurological deficit. Acute flaccid paralysis may occur due to anterior horn cell involvement. A wide variety of movement disorders especially transient Parkinsonian features and dystonia (limb, axial, orofacial) are reported in 20 to 60 percent patients. JE mainly affects thalamus, corpus striatum, brainstem and spinal cord as revealed by MRI and on autopsy studies. (Misra and Kalita 2010) A few studies have documented sequel for in patients' followed up to 3 to 6 months. As such about 28 percent cases have shown to have moderate and about 30 percent patients have severe sequel (Ooi et al 2008). In the clinical course of the disease patients have symptoms of fever, nausea, or headache (Chen et al 2009). In addition, during acute illness restricted eye movements, opsoclonus, upbeating nystagmus, and cogwheel rigidity may be seen. There was early and complete recovery of consciousness and eye signs. Parkinsonian features such as positive glabellar tap sign, mask like face, bradykinesia, tremors, and postural instability became apparent as these patients started walking. Reversible mutism was observed in three patients during the acute phase (Pradhan et al 1999) as a secondary feature. The diagnosis of markedly severe dystonia was based on increasingly frequent episodes of generalized dystonia with bulbar, respiratory, or metabolic derangement

or leading to exhaustion or pain. It was associated with marked axial dystonia resulting in opisthotonus and retrocollis in five patients, jaw-opening dystonia, teeth clenching, and oculogyric crisis and neck deviation, severe spasticity and rigidity in five patients, and focal muscle wasting (Kalita and Misra, 2000). This has become one of the differential diagnostic features for JE and non JE AES in recent times.

Pathological and radiological changes have been mainly restricted to thalamic region as evidenced by various CT and MRI studies. Leptomeningeal enhancement and low density lesions were the most common computed tomography findings. T2 hyperintensity lesions and leptomeningeal enhancement were seen in 5 patients. Two patients presenting with acute flaccid paralysis had high intensity lesions on the thalamus and basal ganglion (Chen, 2009) the presence of thalamic abnormalities suggested the diagnosis of JE but their absence did not exclude it. (Dung et al 2009) The EEG and MEP changes were also more frequently abnormal in the JEV group; however, there was no laboratory evidence of JE virus infection in patients with isolated brainstem involvement (Misra et al 2003). In study, using photon emission tomography (SPET), brain perfusion abnormalities observed depended on the stage of the disease. In the acute stage there was focal hyperperfusion to sites of the brain where JE virus is considered to replicate. In the subacute stage focal hypoperfusion was found to be possibly due to virus induced damage of cellular protein synthesis and in the chronic stage perfusion returns to normal due to regeneration of cellular organelles. Our results also confirm the high frequency of thalamic involvement in JE (Barai et al 2006).

In postmortem brain study edema, perivascular inflammation, hemorrhage, microglial nodules and acellular necrotic foci, as has been described. In addition, there was evidence suggestive of viral replication in the vascular endothelium, with endothelial cell damage; uneven binding of the vascular endothelial cells to Ulex europaeus agglutinin I and ultrastructural changes. There was an active astrocytic response, as shown by glial fibrillary acidic protein staining and activation of microglial cells was demonstrated by an increase in major histocompatibility complex class II expression (German et al 2006)

Therapy

No specific antiviral therapy is currently available, and management of patients is undertaken based on the symptoms. Interferon alpha-2a was tested in a double-blind placebo-controlled trial on children with Japanese encephalitis but with negative results (Gould et al 2008). Interferon inducing agents like aloe-emodin (Lin et al 2008), have shown some results in mouse models. Similarly, minocycline (Mishra et al 2009), Curcumin (Dutta et al 2009) and arctigenin (Swaroop et al 2008) as anti

oxidant and anti inflammatory agent have shown some promise in mice in protection from JE. Pentoxifylline has been tried in mice and probably showed its effect through the virus assembly (Sebastian et al 2009). Many of these drugs need to be tried in controlled trials under medical supervision.

Transmission and Vector Control

The emergence of JE can probably be explained by two factors. First, JE-endemic countries experienced an unprecedented population growth in recent decades. For example, in Eastern Asia, South-Central Asia, and Southeast Asia, the population more than doubled, from 1.7 billion in the mid 1950s to 3.5 billion 50 years later (UN Report, 2005). Second, rice-production systems, particularly irrigated rice farming, have increased both in cropping area and cropping intensity. Today, the total rice-harvested area of all JE-endemic countries (excluding the Russian Federation and Australia) is 1,345,000 km², an increase of 22 percent in the past 40 years.

Predicting outbreaks of JE based on the ecological conditions and mosquito density has always been difficult. In addition, ascertaining the infectivity was difficult. Antigen capture ELISA and recently quantitative RTPCRs have been used. (Samuel et al 2010, Yang et al 2010) Efficiency of field testing of these assays in predicting the outbreaks needs to be monitored. Using the remote sensing, satellite imagery and related techniques, large scale prediction of the outbreaks is being tried. The analysis of these methods in South Korea presented a statistically significant linear relationship between the two parameters, proportion of rice field land cover and log₁₀ of the average number of *Cx. tritaeniorhynchus* collected per trap night (Masuoka et al 2010, Richards et al 2010).

Environmental management for vector control, such as alternative wetting and drying of rice fields (also known as intermittent irrigation), can substantially reduce vector breeding while saving water, increasing rice yields, and reducing methane emission (Keiser et al 2005). However, an effective irrigation requires well-organized educational programs, sufficient water at specific times during the rice-growing cycle and an adequate infrastructure. Environmental management measures are most viable if they are readily integrated into a broader approach of pest management and vector management (WHO Report, 2008). Chemical control of vector populations with insecticides such as pyrethroids, organophosphates, and carbamates plays a marginal role in JE control. Although JE vectors are prone to develop insecticide resistance, usually this issue arises with insecticides that are not directly targeted to JE control, but rather are targeted to control of other pests (Karunaratne et al 2000). Relocating of pigs have been thought to help in breaking the transmission, however

a study in Australia indicated that as detection of JEV in mosquitoes after pig relocation could be shown pig relocation did not eliminate JEV risk. (Van den et al 2008) JE has been controlled in South Korea and Japan mainly on the basis of effective vaccination programs, mechanized farming practices and overall increase in the life style (Erlanger et al 2009; Arai et al 2004).

Vaccines

Traditionally, mouse brain derived inactivated purified JE vaccine (Biken) was used in Japan and other parts of the world for a long time. In order to avoid reactogenicity and to reduce the cost of vaccination tissue culture derived vaccines were developed. Currently, three vaccines are licensed or about to be licensed in many countries. 1. Live attenuated SA 14-14-2 vaccine being used in China Nepal, India. An inactivated Vero cell-derived vaccine based on the Beijing-1 strain is developed in Japan by Biken and Kaketsuken. Another promising vaccine candidate is the inactivated whole-virus vaccine IC-51 (Strain SA14-14-2) by the Austrian company Intercell. The third interesting vaccine candidate being in the late stages of clinical trials is the genetically engineered, Chimeric and live-attenuated vaccine ChimeriVax trade mark-JE by the UK/USA-based company Acambis (Paulke-Korinek and Kollaritsch, 2008)

Inactivated JEV vaccine (IC51, Ixiaro) has been licensed in Australia, the USA and Europe. A series of successful Phase III studies has been published. Results indicate a very good safety and efficacy profile. The vaccine promises to become a modern approach to active immunization against Japanese encephalitis (Jelinek, 2009). The single, high-dose regimen of this vaccine resulted in about 60 percent seroconversion rate at 10 days after administration, but it did not reach the almost 100 percent SCR achieved by the 2-dose standard administration at Day 35 (Schuller et al 2009). Vaccine immunogenicity was also observed in pediatric volunteers, with seroconversion rates not significantly different to an active comparator at 56 days post-vaccination (Duggan and Plosker, 2009). Also at 6 months, immunogenicity was higher with IC51 (seroconversion rate [SCR] 95 percent; geometric mean titer [GMT] 84) than other inactivated vaccine with JE-VAX (SCR 74%; GMT:34) At 12 months, the SCR was 83 percent and the GMT(41) remained above the protective titer of 1:10. Most people immunized with IC51 will have protective neutralizing antibody levels for at least a year (Schuller et al 2008, Dubischar-Kastner et al 2010).

Many studies on YF JE Chimeri VAX have been conducted and the vaccine has already being tested in phase II trials across the globe. Safety and immunogenicity of chimeric vaccine has been established (Chokephaibulkit et al 2010). Studies have shown that a single dose of ChimeriVax-JE gives complete protection; the cross-protective immunity elicited with ChimeriVax-JE is durable (>or=5 months) and broad, ChimeriVax-JE remains fully

attenuated in immunodeficient mice lacking type I and type II interferon responses (Lobigs et al 2009). In a long-term study booster dose at the end of 6 months 97 percent volunteers showed a seroprotective titers till month 60 (Nasveld et al 2010)

In China, various studies on attenuated vaccine against JE SA 14-14-2 have been conducted and have been reviewed. In addition to this in recent times, a few trials with single dose vaccine were conducted. In study in Nepal, of the 430 age-sex matched village controls, 234 (54.4%) were vaccinated. The protective effect of vaccine after 12 to 15 months was 98.5 percent (CI 90.1-99.2%) (Ohrr et al 2005) Similarly, in an earlier study, it was observed that among the 219 village controls, 114 had been vaccinated (52.1%) while only one of 20 JE cases had received live-attenuated JE vaccine. Five years after administration of a single dose, SA 14-14-2 provided a protective efficacy of 96.2 percent (CI 73.1-99.9%) (Tandon et al 2007) This was also seen in single dose study in efficacy that none of 20 JE cases had received JE vaccine compared with 326 of 557 age-sex matched village controls. The efficacy of a single dose of JE vaccine was 99.3 percent (CI 94.9-100%) (Bista et al 2001). In order to include JE vaccine in routine immunization and to reduce the cost of administration of vaccine, a combined vaccine trial of measles and JE was conducted in Philippines. It was observed that live JE vaccine and MV administered together are well tolerated and immunogenic in infants younger than 1 year (Gatchalian et al 2008)

In India, various studies on DNA vaccine have been conducted mainly by NII and IISc. (Huang et al 2009; Ramanathan et al 2009) A few studies on baculo virus based vaccine have been also conducted. NIV has a patent of Chimeric T helper B cell peptides that can induce partial protecting in mice (Dewasthaly et al 2001, 2007). NII group has been working on Vero cell based formalin-inactivated JEV P20778 virus vaccine. It induced high levels of protective immunity in mice (Appaiahgari and Vrati, 2004). NIV has been collaborating with Bharat Biotech International Ltd for development of inactivated vaccine using another Indian strain 821564.

The main pillar of JE control is the use of a live attenuated vaccine for humans, which was developed some 40 years ago (Igarashi, 2002). Currently, available JE vaccines are relatively safe and effective, but a drawback is that multiple doses are required (Solomon, 2006; WHO Report, 2008). Effective delivery of the vaccines to poor, rural communities therefore, remains a formidable challenge, and compliance and delivery costs have to be considered (Bharati and Vrati, 2006). Two vaccine candidates are in late-stage clinical development. The first one is a second-generation, live inactivated, single-dose vaccine grown in Vero cells. It is the yellow fever virus-based Chimeric vaccine and will soon enter the market (Solomon, 2006). The second candidate is an attenuated SA 14-14-2 virus strain,

adjuvanted with aluminum hydroxide and also grown in vero cells (WHO Report, 2008; Tauber and Dewasthaly, 2008). The vaccination of pigs represents another potential strategy to control JE but it is not widely used for 2 main reasons. First, the high turnover in pig populations would require annual vaccination of newborn pigs, which would be costly. Second, the effectiveness of live attenuated vaccines is decreased in young pigs because of maternal antibodies (Wada, 1987).

Present Situation

JE is concentrated in China, India, and the Southeast Asian peninsula. In countries such as Bangladesh, Cambodia, India, and Laos, where no specific diagnostic centers, vaccination programs and surveillance systems are in place, the incidence of JE appears to have increased in recent years. One of the major problems in India is correct surveillance of JE. After introduction of AES as a broader category to catch cases, confusion on correct diagnosis has increased. Thus, each government agency maintains different line lists, and the confirmation of cases poor. Thus, understanding the benefit becomes very difficult. In addition, private practitioners and nongovernmental hospitals are not required to report cases to central registry. On the contrary, in China, Japan, Nepal, South Korea, Sri Lanka, and Thailand, where vaccination programs are being implemented and regular surveillance is pursued, the incidence of JE is stable or declining. Despite the availability of WHO supported surveillance, the situation in North Korea, Myanmar, Pakistan, and Papua New Guinea remains largely unknown. However, under-reporting is substantial in most JE endemic countries; hence, it is conceivable that annual JE incidence is considerably higher than heretofore reported. For example, an estimate that used a representative incidence of 25/10,000 (not immunized), and a 1994 population estimate of 700 million children <15 years of age who live in JE-endemic areas suggested 175,000 cases annually with 43,750 deaths, and 78,750 cases with lasting sequel. Adjusted for vaccine coverage, the estimate is 125,000 cases per year (Sutherst, 2004).

In India, SA 14-14-2 was introduced as campaign mode in 2006. Another vaccine drive has been initiated and planned in 2010 and 2011. In addition, it has been made a component of routine immunization program. However, probable poor vaccination coverage, cold chain problems, highlighting of AEFI by media make it difficult for extensive vaccine coverage. This has resulted in lesser control of JE in highly endemic areas like UP. The problem is compounded by emergence of other encephalitic viruses like Enteroviruses and West Nile in Assam respectively.

Conclusion and Outlook

Discovered 125 years ago, JE has spread widely in the 20th century. Almost half of the human population now lives

in countries, where the disease is endemic. JE is a vector-borne epidemic with several features that are typical of an emerging infectious disease. The failure to halt the spread of JE in Asia and the Pacific region, despite the availability of an effective and inexpensive vaccine for 40 years, is of considerable public health concern. One of the main reasons for the proliferation of JE is the ecologic transformation caused by water resources development and management that create suitable breeding sites for vectors and intermediate hosts, which in turn influence, the frequency and transmission dynamics of these diseases (Sutherst, 2004). High-quality data on transmission and incidence of JE are lacking in various countries. Although clinical and serologic methods to diagnose and monitor JE are available, health systems in many developing countries are unable to differentiate encephalitis diagnoses. Examples of countries with successful JE control programs are Japan and South Korea. Before the 1950s, these countries experienced JE outbreaks, but incidence rates have remained stable for >2 decades. The following key control strategies and developments might explain the successful decline of JE in these countries: (1) large-scale immunization programs for humans, (2) pig immunization and the separation of pig rearing from human settlements, (3) changes in agricultural practices (e.g. enhanced mechanization and decrease of irrigated land), and (4) improved living standards (e.g. better housing and urbanization).

It is speculated that JE incidence is increasing mainly in low-income countries. However, because reliable figures about JE emergence are lacking due to the absence of rigorous monitoring systems, more research is needed to support or refute this claim. In any event, lack of political will and financial resources are two important reasons why JE is often given low priority. These factors might explain the paucity of JE immunization programs for children in low-income countries where the disease is endemic. Nevertheless, Sri Lanka and Nepal and Thailand and Vietnam have managed to successfully control JE.

The overall trend of JE has been declining over the past 3 decades and it is anticipated that this trend will continue in the long term. Indeed, China and India influence JE figures on a global scale because most people living in JE-endemic areas are concentrated in these two countries. The incidence of JE in China has declined since 1971, coincident with economic growth and development. Meanwhile, the national JE vaccination program has been integrated into the expanded program on immunization, and at present, >110 million doses of a live, attenuated vaccine (SA14-14-2 strain) are produced annually.

The incidence of JE in India is still increasing, and the case-fatality rate of reported cases is high, i.e. 10 to 30 percent. India currently has embarking on national vaccination program for children 1 to 15 years of age will be immunized. Overall trends for India are difficult to predict

because JE endemicity is heterogeneous and because socioeconomic conditions for control differ substantially from state to state. Coverage of immunization programs and changes in agricultural practices will further influence JE transmission. In Taiwan, for example, the average age for the onset of confirmed JE cases shifted from children <10 years toward adulthood, explained by a high coverage of vaccinated children. Climate change has been implicated in the increase of transmission of several vector-borne diseases.

The culicines that transmit JE are usually highly zoonophilic, and human outbreaks are therefore the result of a spillover of the virus from the animal reservoir into the human population. Studies in Sri Lanka showed that spillovers happen when there is rapid and dramatic buildup of *Culex spp.* populations to the extent that the number of human blood meals passes a threshold after which virus transmission begins. Such rapid buildups are a result of extreme weather conditions or of rice fields in semi-arid areas being flooded before rice is transplanted. Information on vector population dynamics would be very useful in early warning systems and could also help improve targeting of control programs. In conclusion, JE can be controlled, with effective surveillance systems and vaccines playing key roles. Although currently available vaccines are effective, the need for 3 to 4 injections compromises compliance and increases delivery costs (Bharati and Vrat, 2004). The advent of second-generation, cell-culture-derived vaccines will continuously replace mouse-brain and hamster kidney cell-derived vaccines. Such developments will hopefully boost current vaccination programs and deliver safer, more efficacious, and cheaper vaccines that comply with regulatory norms. Political will and commitment, financial resources, intersectoral collaboration (between the Ministries of Health and Agriculture and other stakeholders to set up vaccination programs for young children), as well as changing agricultural practices, pig vaccination, rigorous monitoring, and surveillance will go a long way in controlling JE.

Influenza Vaccines

Sayan Chatterjee, AK Dutta

Influenza viruses are responsible for respiratory infections and are important cause of mortality and morbidity among persons of all ages worldwide. Influenza viruses belong to the Orthomyxoviridae family of single-stranded RNA viruses, which include Influenza virus types A, B, and C. Influenza A and B cause majority of human infection.¹ Most seasonal local outbreaks and all worldwide outbreaks (pandemic) are due to Influenza A.¹ Last pandemic was seen in 2009. In April 2009, a novel influenza A virus (H1N1) emerged from Mexico² and has spread to other parts of world through human to human transmission so quickly that by June 11, 2009 World Health Organization (WHO) declared this as pandemic.³ This was the first influenza pandemic of this century and fourth overall since first influenza pandemic was recorded during World War I.⁴ Though 2009 H1N1 influenza pandemic officially ended on August 2010, but it is expected to be the predominant influenza virus that will remain responsible for influenza cases over next few flu seasons.⁵

MICROBIOLOGY

Although there is only one influenza B subtype, influenza A viruses are diverse and are characterized by combinations of their hemagglutinin (HA) and neuraminidase (NA) proteins, these are antigenic projections from the virus surface that facilitate viral entry and exit from human respiratory epithelial cells.⁶ There are 16 HA and 9 NA subtypes of influenza A, and although all can affect avian species, H1–3 and N1 and 2 are the principal antigenic types found in humans.¹ Influenza strains are additionally sub classified according to time and place of first isolation (e.g. A/California/7/04 strain).¹

Unlike most respiratory viruses, influenza viruses have evolved efficient mechanisms that promote antigenic variability. Point mutations in the surface protein genes of influenza, particularly the HA gene, can occur at a high

rate during viral replication and confer a selective advantage by facilitating evasion of host immune responses.⁶ Recent data also demonstrate that antigenic changes favorable to the virus can occur in non-immune individuals (particularly children) merely through binding to host cell receptors.⁷ This gives rise to new influenza strains of the same HA type, a phenomenon termed antigenic drift.⁸ These changes may render the host more susceptible to infection because existing antibodies may fail to protect against the new variant. A second mechanism of variation, known as antigenic shift, is less frequent but more dramatic and can occur either through cross-species transmission (e.g. poultry to humans) or by mixing of viral genes when there is simultaneous infection by more than one strain of influenza in a single human or nonhuman host.^{6,8} The influenza genome is segmented, allowing for the reassortment of genome segments so that one influenza strain (such as H3N1) can acquire a completely new HA or NA gene (such as H1 or N1) resulting in a new virus subtype (such as H1N1 or H1N2). These dramatic and sudden changes in influenza serotypes can result in pandemic influenza, particularly if hosts have no pre-existing protective immunity to the new virus and if there is ready spread from person-to-person in a sustained manner. Variability in influenza antigenicity necessitates annual modifications of influenza vaccines.⁸

Despite the potential diversity of influenza viruses, the predominant influenza strains that have caused epidemics and pandemics derive from only four HA subtypes: H1N1, H1N2, H2N2, and H3N2.^{1,6} Globally, the most common circulating influenza A viruses from 1994 to 2005 were H3N2 (90.6%), H1N1 (8%).⁹ However, this distribution changed significantly with the emergence and spread of the 2009 H1N1 pandemic virus;⁶ between April 2009 and March 2010 in the United States, 98% of the influenza A strains typed were the pandemic H1N1 strain.¹⁰ This was

the result of a triple reassortment (avian/human/swine) of recent North American H3N2 and H1N1 swine viruses and Eurasian avian-like swine viruses, followed by cross-species transmission from pigs to humans. It is antigenically distinct from other human and swine H1N1 influenza viruses¹¹ and by the end of the pandemic in August 2010 had caused >600,000 laboratory confirmed cases of infection.¹¹ The 2009 H1N1 virus strains are now considered the predominant seasonal influenza A strains; seasonal H1N1 virus strains have rarely been detected worldwide since 2009.¹²

EPIDEMIOLOGY

Influenza is one of the most common and important respiratory illnesses affecting all ages. In temperate countries, influenza exhibits a seasonal pattern, with peak activity during the winter months (December through March), and local outbreaks generally lasting 6 to 8 weeks before abating.¹³ The epidemic characteristic is less apparent in tropical countries.¹⁴ Influenza A predominates in most seasons, but epidemics of influenza B can occur.^{15,16} Infections typically spread throughout the general population via outbreaks in schools, nursing homes, and hospitals. The virus is stable in low humidity and at cold temperatures, conditions that favor its transmission.¹⁷ This in addition to the indoor crowding that occurs in winter months, could explain the seasonal pattern of influenza infections. The virus grows to high titer in respiratory secretions, promoting efficient transmission among persons in close contact via large particle droplets generated by coughing and sneezing.¹⁸ Small particle airborne transmission in the vicinity of an infected person may also occur.¹² These mechanisms, in addition to direct person-to-person spread by contact with respiratory secretions, or indirect spread through contact with virally contaminated surfaces where virus can persist for hours,¹⁸ account for the explosive nature of influenza outbreaks.

Influenza viruses infect on average 10 to 15% of the U.S. population annually,^{8,19,20} with rates of illness highest among children.²¹ Attack rates during outbreaks can be more than 40%, particularly among children and those with underlying medical conditions.²¹⁻²³ Seasonal influenza epidemics from 1976 through 2004 were responsible for >200,000 annual hospitalizations and >30,000 influenza-associated deaths annually in the United States.²⁴

However, there is significant variability by season, with H3N2-dominant years being associated with higher pneumonia and death rates than H1N1 years. The influenza death toll is considerably higher during pandemics compared with local epidemics,²⁵ due to the large numbers of persons infected and the lack of protective immunity against the new virus subtype. Pandemics occur infrequently (11 have occurred in the past 300 years) but can be devastating.²⁶ Recent global pandemics include those

of 1918–19 (Spanish flu, H1N1; responsible for 50 to 100 million deaths worldwide),²⁷ 1957–58 (Asian flu, H2N2; >1 million deaths), and 1968–70 (Hong Kong flu, H3N2; >700,000 deaths).²⁶ During the spring of 2009, a novel influenza A H1N1 virus of swine origin caused human infections, with a high fatality rate among previously healthy young and middle-aged persons.^{28,29} Despite initial concerns about a high lethality rate with this novel strain,^{28,29} most illnesses caused by the 2009 H1N1 virus were mild and self-limited.^{23,30} Overall case fatality rates were <0.5%.³¹

CLINICAL FEATURES

Following an incubation period of 2 to 5 days, the onset of symptoms of influenza is generally abrupt, a feature that can distinguish the virus from other viral respiratory infections. However, more gradual symptom onset may also occur.³² Fever is the most common finding, present in >90% of cases; other symptoms include a dry, non-productive cough (>80%), nasal congestion or rhinorrhea (>80%), headache, nonexudative sore throat and constitutional complaints (e.g. myalgias, malaise, fatigue, prostration).³²⁻³⁴ In previously healthy individuals, symptoms typically subside without treatment within 5 to 8 days. The course may be more protracted, and complications more frequent, in high-risk or immunocompromised patients.³⁵⁻³⁸ In addition, features of influenza often vary depending upon age. Attack rates are higher in children than in adults, maximal temperatures tend to be higher among children, and children more often have cervical adenopathy.³² Older adults may present with atypical symptoms such as malaise and confusion, lacking typical respiratory symptoms, although pulmonary complications are much more frequent in the elderly.³²

The risk factors for severe infection due to H1N1 influenza are also similar to seasonal influenza and include different chronic underlying medical conditions such as heart, lung, renal and liver disease, neurological and neuromuscular disorders, cancer, immunosuppression, as well as pregnancy.^{39,40} In addition, among patients with pandemic influenza compared with those with seasonal influenza (16% vs 1%) pregnancy was more frequent as was morbid obesity (body-mass index around 40) and American Indian/Alaska. Native race/ethnicity were risk factors for complications from 2009 H1N1 infection.^{12,22} However, there appears to be a shift of hospitalization and death cases to the younger age groups among those infected with H1N1 compared to seasonal influenza.² The age distribution and severity of disease are similar in different countries. CDC data as of July 31, 2009 showed the highest infection rate occurring in persons 5–24 years; the median age of confirmed influenza cases is 12 years.⁴¹ The incidence is lowest in people ≥65 years. The median age of hospitalized patients with H1N1 influenza is 20 years,

while the median age of deaths was 37 years and the highest rate of hospitalization was among children younger than 4 years. In contrast to seasonal influenza, the rates of hospitalization and death from H1N1 influenza were unexpectedly low in adults ≥ 65 years; 5% and 8% respectively.⁴¹

Persons with influenza may develop primary influenza pneumonia or secondary bacterial infection.^{32,42} Radiographic findings due to primary influenza pneumonia may be unimpressive relative to the degree of hypoxia that occurs.^{32,43} Acute respiratory distress syndrome (ARDS) may develop, likely mediated by a virus-induced cytokine storm.⁴⁴ Primary influenza pneumonia, characterized by diffuse interstitial infiltrates, severe hypoxia, and high mortality, is unusual except during pandemics or in individuals with chronic pulmonary disorders or valvular heart disease and increased pulmonary vascular pressure.^{22,32} Secondary bacterial pneumonia may complicate influenza.^{13,42} *Staphylococcus aureus* or *Streptococcus pneumoniae* infection, often with empyema,⁴² may occur 7 to 21 days following resolution of influenza infection. This heightened susceptibility to bacterial respiratory tract infections may be due to increased adherence of bacteria to influenza virus-infected respiratory epithelium,⁴⁵ decreased mucociliary clearance,³² and impaired function of polymorphonuclear leukocytes, macrophages, lymphocytes, and monocytes.⁴²

Non-respiratory complications of influenza are relatively infrequent but can be devastating. Encephalopathy, pericarditis, and rhabdomyolysis with renal failure may occur.⁴⁶ Central nervous system complications (e.g. encephalitis, myelitis, Guillain-Barré syndrome (GBS), and postinfectious encephalitis) are more common in children than adults.^{47,48} Reye syndrome, which is associated with a variety of viral infections, is perhaps the most severe postinfectious complication of influenza. It occurs primarily in children and manifests as neurological impairment, including delirium, seizure and coma, vomiting, respiratory arrest, and liver dysfunction with fatty infiltration.⁴⁹

Influenza and serious complications of influenza are more common in the elderly (age >65 years), children aged <2 years, adults or children with concurrent illness (e.g. pulmonary, cardiac, metabolic), immunosuppressed persons, and residents of chronic care facilities.^{12,32} Pregnant women are at increased risk for severe primary influenza pneumonia with respiratory failure, particularly during the third trimester.⁵¹ This was true of the 2009 H1N1 influenza pandemic; pregnant and postpartum women experienced severe disease and mortality related to influenza.⁵⁰

DIAGNOSIS

Most patients with influenza either fail to seek medical care due to self-limited nature of the disease or never

have the infection confirmed microbiologically when seen by their health care provider. However, laboratory diagnosis of influenza may be useful for management; targeted therapy can be initiated and unnecessary antibiotics avoided, infection control measures can be implemented, excess testing may be minimized, and health care costs can be reduced.^{1,52} Virus typing is also critical for disease surveillance and vaccine development.

An additional argument for using laboratory testing to confirm an influenza diagnosis is that the clinical diagnosis of influenza in all age groups is difficult to make and prone to error.^{53,54} This is in part because the sensitivity of clinical predictors depends on many factors, including influenza prevalence, age, underlying disease, vaccination rate, and duration of symptoms prior to presentation.^{55,56} The World Health Organization definition for influenza like illness (ILI), consisting of acute fever of $>38^{\circ}\text{C}$ and cough or sore throat in the absence of another diagnosis, was demonstrated to have a sensitivity of only 50 percent and specificity of 87 percent in differentiating 2009 H1N1 influenza from non-influenza illness in adult patients.⁵⁵ The clinical accuracy of diagnosing influenza may be much lower in children.^{54,57}

The gold standard for diagnosis was viral culture. Influenza virus can be isolated from nasal, nasopharyngeal swabs or oropharyngeal swab or combination of these are used.^{32,58} Endotracheal aspirate or bronchoalveolar lavage are taken for intubated patient. The swabs used are Polyester or Dacron swab that have a plastic shaft with synthetic tips. Cotton swab with wooden shaft are not recommended. Specimens are then immediately placed in viral transport medium and kept at a temperature of 4°C during transport to laboratory.⁵⁹ But the problem with virus culture are virus isolation is time consuming, taking 3 to 10 days using tissue culture^{60,61} and expensive and thus not always available. Moreover, although virus titers are often high early in the illness but they fall rapidly and culture may become negative only after 72 hours of symptoms.^{32,61} In one study, only 48 percent of hospitalized elderly persons with influenza confirmed by other diagnostic methods had a positive culture,⁵⁴ and the sensitivity of viral culture ranges in various studies between 50 and 90%.⁶¹ So a negative culture does not rule out infection.

Serological testing by detecting antibodies on paired acute (obtained within 1 week of disease onset) and convalescent (obtained 2 to 3 weeks later) sera, are used to diagnose retrospectively for epidemiological and research purposes but are not useful in the acute care setting.¹

The availability of easy-to-use rapid influenza diagnostic kit that detects viral antigens in respiratory secretions has improved the ability to rapidly diagnose influenza. Direct and indirect immunofluorescence assay are mostly used. These tests are relatively inexpensive, requires less infrastructure and usually provide result in around 1 hour

with a sensitivity of 50 to 90% and a specificity of 95% depending on the incidence, type of specimen and duration of symptoms prior to testing.^{1,61} These tests usually differentiate between influenza A and B infections.⁶² A patient with novel influenza A 2009 H1N1 may test positive for influenza A by the rapid tests but positive test for influenza A cannot differentiate between seasonal and novel influenza A 2009 H1N1 viruses.⁶³ The sensitivity and specificity of rapid tests for diagnosis of novel influenza A 2009 H1N1 is unknown. Initial studies suggest that sensitivity of rapid tests is significantly less compared to polymerase chain reaction in diagnosing novel influenza A 2009 H1N1.⁶⁴ So, a negative test does not rule out infection or an outbreak and rapid diagnostic tests are not essential in patients with typical influenza symptoms during confirmed outbreaks.⁶⁰

Another good method of detection is by detecting viral RNA by reverse transcription-polymerase chain reaction (RT-PCR). This is more sensitive than viral culture or antigen testing and has replaced culture as the gold standard for diagnosis.^{1,12,33,61} But, this testing is costly and not available widely.

Guidelines on categorization of Influenza A H1N1 Pandemic Novel Influenzas cases during screening for home isolation, testing treatment, and hospitalization by Govt. of India (Revised on 05.10.09).

In order to prevent and contain outbreak of Influenza-A H1N1 virus for screening, testing and isolation following guidelines are to be followed:

At first all individuals seeking consultations for flu like symptoms should be screened at healthcare facilities both Government and private or examined by a doctor and these will be categorized as under:

Category A

- Patients with mild fever plus cough/sore throat with or without body ache, headache, diarrhea and vomiting will be categorized as

Category-A: They do not require Oseltamivir and should be treated for the symptoms mentioned above. The patients should be monitored for their progress and reassessed at 24 to 48 hours by the doctor.

- No testing of the patient for H1N1 is required.
- Patients should confine themselves at home and avoid mixing up with public and high risk members in the family.

Category B

- In addition to all the signs and symptoms mentioned under Category-A, if the patient has high grade fever and severe sore throat, may require home isolation and Oseltamivir;
- In addition to all the signs and symptoms mentioned under Category-A, individuals having one or more of

the following high risk conditions shall be treated with Oseltamivir:

- Children with mild illness but with predisposing risk factors.
- Pregnant women;
- Persons aged 65 years or older;
- Patients with lung diseases, heart disease, liver disease, kidney disease, blood disorders, diabetes, neurological disorders, cancer and HIV/AIDS;
- Patients on long term cortisone therapy.
- No tests for H1N1 is required for Category-B (i) and (ii).
- All patients of Category-B (i) and (ii) should confine themselves at home and avoid mixing with public and high risk members in the family.

Category C

In addition to the above signs and symptoms of Category-A and B, if the patient has one or more of the following:

- Breathlessness, chest pain, drowsiness, fall in blood pressure, sputum mixed with blood, bluish discoloration of nails
- Children with influenza like illness who had a severe disease as manifested by the red flag signs (Somnolence, high and persistent fever, inability to feed well, convulsions, shortness of breath, difficulty in breathing, etc.)
- Worsening of underlying chronic conditions

All these patients mentioned above in Category-C require testing, immediate hospitalization and treatment.

TREATMENT

Influenza is generally a self-limiting illness that does not require any antiviral therapy, whether caused by seasonal influenza strains or by novel 2009 H1N1 strain. Antiviral treatment is recommended for suspected or confirmed influenza with severe, complicated or progressive illness or those who require hospitalization.^{12,58} Treatment is also recommended in outpatients with confirmed or suspected influenza if they are at risk for complications based on age (less than 2 yr or more than 65 yr), with underlying chronic medical conditions, pregnancy and immunocompromised patients.^{12,58} The optimal benefit of these medications occurs if they are administered within the first 48 hours of symptoms,⁵⁸ and they can reduce both the duration and severity of illness as well as the chance to develop severe disease or death.^{22,65-68} Although early initiation of antiviral therapy (within 48 hours of symptom onset) is required for optimal benefit, recent data have indicated benefit even in those who start treatment after 48 hours of symptom onset.^{67,69,70}

Two groups of drugs are currently available as anti-influenza medication. These include the adamantanes (Amantadine and Rimantadine) and newer neuraminidase

inhibitors (NAI) (Oseltamivir, Zanamivir and Peramivir). These two groups of drugs differ in pharmacokinetic properties, safety profile and sensitivity.

Adamantanes

Amantadine and rimantadine prevent viral replication within infected cells by blocking the influenza A virus M2 ion channel protein.⁷¹ Influenza B virus also got similar ion channels, but the adamantanes are ineffective against influenza B. Both were shown to be effective to treat^{16,72} uncomplicated infections due to sensitive influenza A. Overall, the duration of illness is shortened by around 1 day with either agent.⁷³ They were also found to be effective in prophylaxis.⁷⁴⁻⁷⁶ Adamantanes are associated with central nervous system toxicity (e.g. anxiety, insomnia, depression, hallucinations, seizures) as they stimulate catecholamine release, but rimantidine does not cause catecholamine release and CNS toxicity are not seen in them both can cause nausea, vomiting, and dyspepsia.^{73,75}

Unfortunately, widespread resistance to adamantanes among influenza A viruses has virtually eliminated the use of these drugs. Resistance can result from a single amino acid substitution within the viral M2 protein,^{9,77} and cross-resistance between amantadine and rimantadine is complete.^{73,78} In 2009 pandemic, resistance was detected among all 2009 H1N1 viruses tested in USA,⁷⁹ and high levels of resistance have been seen worldwide.⁹ Many treated patients shed adamantane-resistant influenza virus in the later stages of illness and this can result in outbreaks with drug-resistant virus. Therefore, the use of adamantanes for treatment or prophylaxis of current influenza viruses has been discouraged.^{12,80,81}

Neuraminidase Inhibitors (NAIs)

Currently NAIs are the drug of choice for prophylaxis and treatment of influenza. Apart from some sporadic cases, viral surveillance data indicate more than 99 percent influenza virus are still susceptible to NAIs. US FDA approved drugs are Oseltamivir and Zanamivir. They inhibit the viral NA enzyme by mimicking its natural substrate, N-acetylneuraminic acid (also called sialic acid), the cell surface receptor for influenza.⁸² Viral NA removes sialic acid from cell surface glycoproteins and thereby releases progeny influenza virus from infected host cells.⁷³ Neuraminidase inhibition leads to persistent attachment of virus to the host cell; viral replication and intensity of infection are thus reduced.⁷³ NAIs are active against both influenza A and B, but they are less active against influenza B.^{15,83,84} In comparison to adamantanes, NAIs have little toxicity. Whereas Oseltamivir is given by oral route, Zanamivir is given by inhalational route by dry powder inhalation. Dosing is similar to what is given in seasonal influenza and duration of treatment is 5 days. Long term therapy may be given in hospitalized patient with severe persistent

symptoms. Peramivir, another NAI, is under Phase 3 trial, given by Intravenous route was used in 2009 H1N1 pandemic to treat severely ill hospitalized patient successfully. Early treatment with NAIs was shown in randomized, controlled trials to shorten the course of illness.^{65,85-88} Duration of symptoms is typically decreased by 1 to 2 days in patients receiving NAIs compared with those receiving placebo,^{65,83,85,88} NAIs also reduce complications of influenza,⁸⁹ including sinusitis, bronchitis,⁸⁷ and otitis media.⁸⁸

Prophylaxis

Oseltamivir or Zanamivir is used for prophylaxis, in half dosage to what is used for treatment for total 10 days.⁹⁰ Prophylactic treatment is not indicated for healthy adult or children due to potential exposure in school or community. Prophylaxis is indicated for 'at risk' individual who may develop severe complication have been in contact with a person who have been diagnosed or suspected of having H1N1 influenza. Prophylaxis is also advocated for health care worker who come in close unprotected contact with diagnosed case of H1N1 influenza. Prophylaxis should be given within 48 hrs of exposure.⁹⁰

INFLUENZA VACCINE

Cornerstone for prevention of influenza and its complication is vaccine. In case of influenza, immunity response is provided by antibodies to surface antigen, particularly to HA antigen. But the problem is that antibody to one influenza type or subtype or antigenic variant confers little or no protection against other influenza types or subtypes or antigenic variant of the same type or subtype.⁹¹ Due to antigenic drift, this antigenic variant is quite frequent in influenza virus. But influenza vaccines are targeted against such an antigen which is prone to change therefore vaccines must be reformulated annually based on the changing pattern of influenza virus. This input regarding the changing pattern of influenza virus is usually given by World Health Organization (WHO).⁹² In February and September of each year, for the Northern and Southern Hemispheres, respectively, the influenza virus strains to be included in the coming season's vaccine are selected.⁹³ Two strains of influenza A (one H3N2 and one H1N1) and one of influenza B are selected and mixed in each vaccine to elicit broad serum immunoglobulin G (IgG) responses against surface HA and NA proteins of circulating strains. However, if significant antigenic change occur after this, as occurred in 2009, the vaccine may fail to cover the circulating influenza strains.⁹⁴ Another problem is, the current technology for developing influenza vaccines (i.e., egg-based manufacturing) is slow and existing supplies of vaccines can be inadequate in the face of a global pandemic.⁹⁵ As evidence of this, in response to the beginning H1N1 pandemic, the WHO made recommendations for vaccine strains in May 2009, but the virus replicated

poorly in embryonated chicken eggs, leading to vaccine shortages. Though production of vaccine in embryonated eggs has been safe and effective, but cell-culture based vaccine production is more rapid and it would also allow vaccination of persons with egg allergies.⁹⁶

Currently available seasonal influenza vaccines include the trivalent inactivated vaccines (TIVs) and live attenuated influenza vaccine (LAIV).⁹⁷ Both vaccines contain the same antigenic variants of influenza A and influenza B viruses which are predicted by WHO.⁸ Seasonal influenza vaccines are unlikely to protect against 2009 H1N1 influenza due to antigenic variation.^{11,98} It is observed that no cross reactive antibodies to 2009 H1N1 influenza virus developed in children receiving seasonal influenza vaccine.⁹⁸ Specific monovalent H1N1 influenza vaccines have been developed. Similar to seasonal influenza vaccine, both inactivated and live attenuated formulations against Influenza A (H1N1) 2009 are available and these are also produced by replicating the virus in embryonated hen eggs. The vaccines contain the strain A/California/7/2009 (H1N1) pdm.⁴¹ U.S.-licensed influenza vaccines do not contain adjuvants while some vaccine may contain adjuvants (with alum or MF-59) (Table 1).

In June 2010, first ever indigenous H1N1 vaccine was produced in India. This is an inactivated (whole virion) monovalent (H1N1) 2009 influenza vaccine. The vaccine is recommended for 18 years and above and should be administered by a single 0.5 ml intramuscular injection preferably in deltoid region.⁶⁴ Subsequently other indigenous vaccine including nasal live vaccine against influenza (H1N1) 2009 are started to be produced in India.⁹⁹

Whom to Vaccinate

Due to the short supply of influenza vaccine during the initial period of 2009 outbreak, the CDC' Advisory Committee on Immunization Practices (ACIP) recommended priority wise vaccination to five groups considered at the highest risk of influenza complications. These include:

- Pregnant women
- Close contacts of children less than 6 months of age

- Health care personnel
- Children and young adults 6 to 24 years of age and
- Persons 25 to 64 years of age with underlying medical conditions that are associated with increased influenza mortality and morbidity⁴¹

If the vaccine still does not fulfil the requirement of above group, ACIP recommended vaccination to 1st 3 groups. When vaccine becomes available then target population should be vaccinated as early as possible. Since 2010, ACIP started to recommend annual influenza vaccination of all persons ≥ 6 months age.

In India due to financial burden, use of influenza vaccine is very limited. After the pandemic of 2009, currently IAPCOI recommends influenza vaccine in all children with risk factors and also where the vaccine is requested by parents (after discussing benefits and limitations of the vaccine)

At risk individuals

- Congenital or acquired immunodeficiency
- Chronic cardiac, pulmonary, renal, liver, hematological disease and diabetes mellitus
- Children on long-term aspirin therapy
- Any neurologic disease that might cause respiratory compromise or impair the ability to handle secretions

Individual Vaccines (Table 2)

Inactivated influenza vaccines are basically of 3 types viz whole virus, split product and subunit vaccine. Whole virus vaccines are not used due to increased adverse reactions. Currently available vaccines are either split product vaccines (detergent treated) or subunit vaccines containing surface antigens in form of purified hemagglutinin and neuraminidase. Trivalent vaccines contain 15 μg of each of WHO recommended strain. Storage temperature is 2 to 8°C and should not be frozen.

Live attenuated vaccine is made by genetic reassortment of three influenza strains. It is also stored between 2 and 8°C. It is administered by a nasal spray that deposits the vaccine in nose and nasopharynx.

Table 1: Dosing schedule¹⁰⁰

Vaccine type	Age group	Dose	Route
Inactivated	6-35 months	0.25 ml, 1 or 2 doses, 4 weeks apart	Intramuscular
	>36 months	0.5 ml, 1 or 2 doses, 4 weeks apart	
	9 years	0.5 ml, 1 dose	
Live attenuated	2-49 year	0.2 ml sprayer, 1 or 2 doses, 4 weeks apart	Intranasal

* Children aged 6 months through 8 years who did not receive seasonal influenza vaccine during the 2010–11 influenza season should receive 2 doses at least 4 weeks apart for the 2011–12 season. Those children aged 6 months through 8 years who received ≥ 1 dose of the 2010–11 seasonal vaccine require 1 dose for the 2011–12 season. ≥ 9 years 1 dose. Revaccination annually.¹⁰⁰

* For adults and older children, the recommended site of vaccination is the deltoid muscle. The preferred site for infants and young children is the anterolateral aspect of the thigh.¹⁰⁰

Table 2: Comparison between inactivated and live influenza vaccine

	<i>Inactivated vaccine</i>	<i>Live vaccine</i>
Vaccine structure	Purified HA and NA antigen	“cold adapted” virus, ¹⁰¹ meaning it cannot replicate at temp. <25° C and thus is restricted to replicating in the upper airway.
Immune responses, whereas	Higher serum IgG response	Better IgA mucosal response at the site of entry. ⁸
Age of administration	>6 months	Healthy persons aged 5-49 years ¹⁰²
Route of administration	Intramuscular	Nasal
In person with underlying medical condition, pregnancy	Can be given	Not given due to higher risk of complication ¹⁰²

Vaccine Strain for 2011-12 Influenza Season

The 2011–12 U.S. seasonal influenza vaccine virus strains are identical to those contained in the 2010–11 vaccine. These include A/California/7/2009 (H1N1)-like, A/Perth/16/2009 (H3N2)-like, and B/Brisbane/60/2008-like antigens. The influenza A (H1N1) vaccine virus strain is derived from a 2009 pandemic influenza A (H1N1) virus.¹⁰³

Timing of Vaccination

The influenza vaccines should be given before the peak influenza season. In temperate countries the peak influenza season is in winters (December to March), in tropical countries like India illness occurs all over the year. So, the vaccine can be given at any time but generally given as soon as the new vaccine becomes available in the market or at the time of presentation to health care worker. Recently, WHO global influenza surveillance network have shown, in India, influenza peaks during monsoon (June to September). So, vaccine may be administered before monsoon, but new vaccine becomes available in India in late monsoon (around August).

Efficacy

If the vaccine strain match the circulating influenza virus strain, inactivated vaccines provide 70 to 100 percent protection among healthy adults and 30 to 60 percent among the elderly or young children.^{104,105} Serum antibody responses to influenza vaccination may be blunted in the elderly, immunocompromised individuals and preschool children compared with healthy school-age children or adults.⁷³ Protection against viruses similar to those in the vaccine generally lasts 6 to 8 months but can be much longer.⁹¹ A meta-analysis of 25 studies of healthy adolescents or adults (aged 14 to 60 years) found that TIV reduced serologically confirmed influenza by 70 percent compared with unvaccinated individuals.¹⁰⁶ In a study of children aged 5 through 8 years who received trivalent

inactivated vaccine (TIV) for the first time, the proportion of children with protective antibody responses was significantly higher after 2 doses than after 1 dose.¹⁰⁷

Both TIV and LAIV are effective in children and adults, and there are insufficient data to conclude there is an advantage of one over another.⁹¹ A randomized study comparing TIV to LAIV in healthy adults during the 2004–05 influenza season showed that LAIV was less effective than TIV, primarily due to reduced activity against influenza B viruses.⁹⁷ However, in children aged 6 to 59 months, LAIV was shown to be more efficacious than TIV, with 55 percent fewer cases of influenza in the LAIV group.¹⁰⁸ It has been postulated that LAIV may be more effective in young children or vaccine-naïve individuals because it may not replicate as well (and thus stimulate a less effective immune response) in an individual who already possesses some neutralizing antibodies to influenza.¹⁰⁹

The 2009 H1N1 monovalent vaccine was found to have immunogenicity similar to that of typical seasonal influenza vaccines.¹¹⁰

Vaccination in Children

As noted earlier, young children are at high risk for acquiring and transmitting influenza infections.^{13,33,34,111} Several studies in healthy children^{112,113} have demonstrated a 55 to 70 percent reduction in laboratory-confirmed cases of influenza after administration of TIV or LAIV. Both can also reduce the incidence of otitis media in infants.¹¹⁴ Furthermore, the efficacy rate improves from 89 percent with one dose to 94 percent with two doses 60 days apart.¹⁰¹

Vaccination of children in schools can reduce the incidence of influenza among family contacts¹¹² and the community at large.¹¹³ In Japan, implementation of a national child immunization program where >80 percent of school children received influenza vaccine prevented between 37,000 and 49,000 deaths (one death per 420 vaccinated children), principally in the elderly.¹¹³ When vaccination of children subsequently became optional, mortality rates increased. Results from these studies suggest that universal

vaccination of school-age or preschool children should be encouraged to develop herd immunity and benefit the community at large.¹¹⁵

Vaccination in Special Group

- Vaccination of health care workers (HCWs) is highly effective in protecting high-risk patients from influenza.^{116,117} Studies have found that vaccination of HCW in hospital can reduce mortality among hospitalised patient as well as lower worker sick leave.¹¹⁸ The CDC has recommended achieving high influenza vaccination rates of HCWs to prevent transmission between HCWs and patients.¹¹⁹
- Influenza vaccination is beneficial among elderly adults (>65 yr) living in the community or nursing homes.^{34,120} Vaccination was associated with reduction in the rate of hospitalization and mortality for pneumonia and influenza.
- Influenza vaccine also found to be beneficial in adult with concurrent medical illness and other high risk patients like in pregnancy, immunocompromised patient and recommended strongly in these group because of the potential for serious morbidity and mortality.³¹

ADVERSE EFFECT

Clinically important adverse effects are uncommon. With TIV, mild soreness of the arm at the site of vaccination for 1 to 2 days and fever, malaise, headache and arthralgia can occur. Hypersensitivity to other vaccine components can occur but is also very uncommon.⁹¹ Previously GBS was said to be rare adverse effect of influenza vaccination but now it has been shown that GBS was not associated with influenza vaccine. LAIV is well tolerated in children and adults.¹⁰¹ Mild upper respiratory tract symptoms (rhinorrhea, sore throat, nasal congestion) develop in 10 to 15 percent of persons receiving LAIV.^{8,101}

CONTRAINDICATION

Both vaccines are contraindicated in patients who are allergic to eggs, but even in this context serious hypersensitivity reactions to the vaccine are rare.¹²¹ Live vaccine should not be administered to immunocompromised individuals and in pregnancy, although inadvertent exposure to LAIV is not expected to lead to significant adverse events or prolonged viral shedding in persons with chronic medical conditions including human immunodeficiency virus infection.¹²²

CHAPTER 50

Newer and Emerging Vaccines

Dinesh Yadav, AK Dutta

Vaccination is one of the most effective methods of intervention for prevention of diseases without improvement in overall socioeconomic status of a country. It is one of the most rapidly changing fields of medicine. Many vaccines against viral, bacterial, parasitic diseases and malignancies are under development, out of which only few have reached to clinical trials including malaria, dengue, HIV and hepatitis E vaccine. A brief review of new and emerging vaccines of global importance is presented.

MALARIA VACCINE

Malaria is a disease of global importance and afflicts more than 90 countries and territories in the tropical and subtropical regions. The World Health Organization (WHO) estimates 300 to 500 million malaria cases annually, with estimated mortality attributed to malaria ranging from 0.7 to 2.7 million/year globally.¹ Approximately 2.48 million cases are reported annually from South-east Asia, of which 75 percent cases are contributed by India alone. WHO has reported malaria mortality rate 15000 per year from India; however, a recent study by million death collaborators suggest much higher annual malarial mortality from India (205,000 overall and 55000 in children <14 years age).²

RTS,S/AS01 is a hybrid construct of the hepatitis B surface antigen fused with a recombinant antigen derived from part of the circumsporozoite protein. Given in three doses, it is formulated with an adjuvant (AS01 or AS02) and must be maintained in a cold chain³. The vaccine targets the parasite's circumsporozoite protein—the most prominent surface antigen on the sporozoite of the malaria parasite. The RTS,S vaccine triggers the immune system against *Plasmodium falciparum* when it enters the bloodstream or when it infects liver cells. This is the protein coat of the sporozoite, the parasite stage that is inoculated by the feeding anopheline mosquito, which then

invades liver cells and multiplies there before entering the bloodstream. Keys to the success of the vaccine are the immunogenic polymeric nature of RTS,S particles and the proprietary adjuvant AS01⁴. This vaccine has shown protection against *Plasmodium falciparum* malaria in children and infants in initial phase I trials. The vaccine had an acceptable side-effect profile and was immunogenic in children who were 6 weeks of age or older. In addition, the vaccine could be administered safely with other childhood vaccines and provided protection against severe malaria.^{5,6}

First results of recently published phase 3 trial of RTS,S/AS01 vaccine in African children has reported good efficacy and safety against both clinical and severe malaria. This randomized, controlled, double blind trial was designed to evaluate vaccine efficacy, safety, reactogenicity, and immunogenicity in children 6 to 12 weeks and 5 to 17 months of age after the administration of malaria vaccine. Initial results of the trial included 6000 children aged 5 to 17 months old enrolled at 11 centers in seven African countries. They were randomized to three doses of the new vaccine at one month intervals or a non-malaria comparator vaccine. During 12 months of follow-up, the incidence of the first or only episode of clinical malaria meeting the primary case definition was 0.44 per person-year in the RTS,S/AS01 group and 0.83 per person-year in the control group, resulting in a vaccine efficacy of 55.8 percent (97.5% confidence interval [CI], 50.6 to 60.4). At least one episode of severe malaria that met the primary case definition occurred in 57 of 2830 children (2.0%) in the RTS,S/AS01 group and in 56 of 1466 children (3.8%) in the control group, for a vaccine efficacy of 47.3 percent (95% CI, 22.4 to 64.2). Among children in the combined age categories, at least one episode of severe malaria that met the primary case definition occurred in 149 of 8597 children (1.7%) in the RTS,S/AS01 group and in 116 of

4364 children (2.7%) in the control group. Thus this anti-malarial vaccine halved the number of first clinical episodes of malaria and severe malaria in children in the 12 months after vaccination. The vaccine's protection was lower at the end of 12 months, suggesting that a booster may be needed. Results of one year efficacy in children aged 6 to 12 weeks are expected late next year and final efficacy and safety data for both age groups are expected in late 2014.⁷

Among adverse events, generalized convulsive seizures in the 7 days after RTS,S/AS01 vaccination occurred at a rate of approximately 1 per 1000 vaccine doses, a higher rate than that seen with the comparator rabies vaccine. All cases were associated with a history of fever, and all children recovered from the acute event. This increased risk of febrile reactions or seizures among RTS,S/AS01 recipients may be real, reflecting the reactogenicity of this highly immunogenic vaccine. Besides this, meningitis was reported more frequently in the RTS,S/AS01 group than in the control group, for a relative risk of 5.5 (95% CI, 0.7 to 42.6) in the older age category and 4.0 (95% CI, 0.5, 32.0) in the younger age category. There seems to be no plausible explanation for this, and it may well turn out to be a chance finding, but it cannot be ignored. Such questions highlight the importance of phase 4 studies of both safety and effectiveness with active surveillance if this vaccine is deployed.

These initial results show that the RTS,S/AS01 vaccine reduced malaria by half in children 5 to 17 months of age during the 12 months after vaccination and that the vaccine has the potential to have an important effect on the burden of malaria in young children. Additional information on vaccine efficacy among young infants and the duration of protection will be critical to determining how this vaccine could be used most effectively to control malaria.⁷ Although the vaccine is not 98 to 99 percent effective, as some vaccines against other diseases are, it may be further improved and is an important start in reducing malaria.

DENGUE VACCINE

Dengue viral infection has become an increasing global health concern with over two-fifths of the world's population at risk of infection. Dengue is a tropical disease affecting 110 countries throughout the world and placing over 3 billion people at risk of infection, affecting predominantly children. According to the World Health Organization 70 to 500 million persons are infected every year including 2 million who develop hemorrhagic form and 20,000 who die. It is the most rapidly spreading vector borne disease, attributed to changing demographics, urbanization, environment, and global travel. Dengue also carries a hefty financial burden on the health care systems in affected areas, as those infected seek care for their symptoms.^{8,9}

Due to the absence of specialized laboratories in most endemic regions and to the lack of specific clinical presentation, the incidence of dengue and its economic costs are certainly underestimated. Dengue is caused by an arbovirus belonging to the Flavivirus genus of the family Flaviviridae. There are four dengue virus serotypes and no cross protection between them. The disease is transmitted through the bites of mosquitoes belonging to the *Aedes* genus, mainly *Aedes aegypti*. There is no specific treatment for dengue. Prevention requires control of vector mosquitoes that is difficult to implement and maintain. The high human and economic costs as well as the absence of specific preventive measures underscore the need to develop a vaccine. However finding and distributing such a vaccine to populations at risk is hampered by numerous obstacles. The most notable challenges standing in the way of development of a candidate vaccine are as follows: absence of an animal model, which has important implications for the preclinical development strategy; need to develop a live attenuated vaccine; existence of 4 antigenically distinct serotypes with the resulting risk of competition between vaccine strains; immunologic risks related to antibody-dependent enhancement that has been hypothesized to be the cause of severe forms of the illness; absence of a well defined correlate of protection and preexisting vaccine, which will require the organization of large-scale preclinical trials to demonstrate the efficacy of the virus; complexity associated with industrial production of a tetravalent vaccine. Development and production of a safe and reliable vaccine are only the first steps to ensuring protection of the populations at risk.

Strategies with traditional attenuation, chimerization, engineered attenuation are in the more advanced stages. In addition, inactivated, subunit, virus-vectored, pseudo-infectious virus, DNA vaccines and recombinant subunits have been developed.¹⁰ The candidates include live attenuated tetravalent vaccines, chimeric tetravalent vaccines based on attenuated dengue virus or yellow fever 17D, and recombinant DNA vaccines based on flavivirus and nonflavivirus vectors.¹¹ Phase II clinical trials are now under way in children and adults in Mexico, Peru, and the Philippines. Similarly, two live attenuated tetravalent vaccine candidates are in Phase II clinical trials in dengue endemic regions. Although some level of success has been attained, several obvious obstacles still exist. For example, live attenuated dengue vaccines must elicit appropriately balanced tetravalent immunity, and they must be characterized by a good safety profile. The inactivated whole virion dengue vaccines were restricted by the low virus yields in typical dengue viral cultures. Recombinant subunit dengue vaccines may provide significant benefits over other approaches. For instance, subunit vaccines eliminate exposure to the virus, which means they are safer, and they are more easily manipulated through dose adjustments to

obtain a balanced immune response to all four serotypes of DV. However, subunit vaccines are recognized as poor immunogens, they require several immunizations and they must be formulated with a strong adjuvant to generate a sufficient immune response.

One of the subunit vaccines using lipidated consensus dengue virus envelope protein domain III (LcED III) have been studied in Taiwan in animal models. Single dose of this vaccine was capable of activating antigen-presenting cells and enhancing cellular and humoral immune responses. Besides this, single-dose of LcED III immunization was reported sufficient to elicit neutralizing antibodies against all four serotypes of dengue viruses in mice without extra adjuvant formulation. In addition, strong memory responses were elicited with quick, anamnestic neutralizing antibody responses to a live dengue virus challenge at 28 week postimmunization. These results demonstrate the promising possibility of a future successful tetravalent vaccine against dengue viral infections that utilizes one-dose vaccination with LcED III. However, this vaccine needs further phase III studies on safety and efficacy.¹²

Recent data suggest that dengue immunity could be elicited via either humoral or cell-mediated routes. Directing the immune response to serotype-specific epitopes from domain (D)III of the dengue virus envelope protein (Env) may induce effective levels of neutralizing antibodies. Removing serotypecross reactive epitopes from DIII, as well as DII, may reduce the potential for the vaccine to induce non-neutralizing antibodies associated with antibody-dependent enhancement (ADE) of infection. The use of consensus Env DIII sequences for each serotype, and perhaps even a single consensus sequence for all four serotypes of dengue virus, may direct the immune response to invariant neutralizing sequences, which might improve vaccine safety and long-term efficacy. Vaccines incorporating capsid and/or nonstructural (NS) proteins may be capable of inducing tetravalent cell-mediated immunity without ADE. However, the potential of cell-mediated immunity to contribute to pathology is not well understood, and modifications of NS proteins, such as truncated NS1, may be necessary for optimal vaccine safety.¹³ As of now, all of these dengue vaccines are under trials and no licensed dengue vaccine is available.

HIV VACCINE

An estimated 25 million people with HIV infection reside in sub-Saharan Africa. In resource poor settings, restricted treatment options and the cost of alternative treatment regimens are likely to magnify the limitations of antiretroviral treatment (ART) programs. Antiretroviral treatment can successfully reduce plasma HIV-1 RNA levels to <50 copies/ml, although it is less effective in those with advanced immunosuppression and higher viral loads.

ART has been linked to abnormalities of body fat metabolism and distribution, hyperlipidemia, insulin resistance, hyperglycemia, and lactic acidosis requiring regimen change in 40 percent of individuals within 1 year of starting treatment.^{14,15}

Therapeutic interventions that enhance immunologic function with concurrent ART may improve the long-term outcome of HIV infection. Immune recovery following appropriate ART is often incomplete and fails to elicit responses associated with protection from disease progression.¹⁶ This failure has been associated with dysfunctional T cell responses. Therefore, boosting the immune response via therapeutic intervention may significantly delay or inhibit progression to AIDS. Therapeutic vaccinations in rhesus macaques have demonstrated that immunity can be elicited, leading to lower viral load.¹⁷ Therapeutic vaccination for HIV is different from other vaccines in way that it primarily given not to prevent disease, but to promote immune recovery and prevent progression to advanced stage.

Prior studies have shown a reduction in plasma viremia in HIV infected individuals and evidence of enhanced HIV specific T cell responses after immunization.^{18,19} LFn-p24C consists of a detoxified anthrax-derived polypeptide, called lethal factor n-terminus (LFn), which has been fused to the HIV subtype C gag protein p24. Therapeutic immunizations using this LFn-p24C vaccine was studied in HIV infected patients from Uganda, Africa. This open label Phase I trial was designed to assess the safety, tolerability and immunogenicity of a therapeutic HIV-1 vaccine candidate. Thirty HIV positive volunteers receiving a stable regimen of antiretroviral therapy with CD4 counts >400 were recruited for the safety evaluation of LFn-p24C vaccine. The vaccine was well tolerated and HIV RNA levels remained undetectable following three immunizations. CD4 counts in vaccine recipients were significantly higher compared to the control individuals after 12 months. HIV-specific responses were associated with higher gain in CD4 counts following LFn-p24C immunizations. Volunteers were subsequently asked to undergo a 30-day period of observed treatment interruption and 30 percent individuals showed no evidence of viral rebound during treatment interruption. All demonstrated prompt suppression of viral load following resumption of ART. These initial data demonstrate the safety of LFn-p24C and suggest that adjunct therapeutic immunization may benefit select individuals in further boosting an immune response.²⁰ However, further phase II and III trials are required to establish role of therapeutic immunization in HIV infected patients.

HEPATITIS E VACCINE

Clinically indistinguishable from other types of acute viral hepatitis, hepatitis E virus (HEV) tends to be self-limited

and usually does not become chronic. A substantial majority of clinically apparent acute viral hepatitis among adults in much of Asia, the Middle East and North Africa is caused by HEV. An estimated one-third of the world's population living in the developing countries has been infected with HEV. Outbreaks of hepatitis E have been documented over a wide geographic area, primarily in developing countries with inadequate environmental sanitation; some of the large outbreaks involving tens of thousands of cases have occurred in India, China, and more recently in Uganda. In endemic areas hepatitis E predominantly affects adolescents and young adults aged 14 to 40 years with an overall fatality rate of 1 to 3 percent, however, pregnant women have a poor prognosis with mortality rates of 5 to 25 percent, and survivors have high rates of spontaneous abortion and stillbirth.²¹ In India, the lifetime infection risk is more than 60 percent, which translates to hundreds of thousands of illnesses annually. In patients with chronic liver disease, superinfection with hepatitis E virus often leads to a poor outcome. Every year, 13,000–26,000 deaths are estimated in patients with chronic liver disease in industrialized countries.²² Of particular concern in these countries is the development of chronic liver diseases among organ transplant recipients, HIV infected and other immunocompromised individuals infected with HEV.

At least four genotypes of hepatitis E viruses have been identified. Genotypes 1 and 2 were isolated from human beings and are mainly seen in developing countries. Genotypes 3 and 4 are zoonotic, with pigs being the principal reservoir; they have been identified in many sporadic cases and limited food borne outbreaks mainly affecting middle-aged and elderly men. Nevertheless, all hepatitis E viruses associated with human diseases can be considered as belonging to one serotype.²²

Natural infections in humans and experimental HEV infections in animal models elicit an antibody response which results in protective immunity. Rechallenge and passive immunoprophylaxis studies in animal models (macaques) have shown that antibodies to HEV can protect against HEV infection and hepatitis. Further, there is epidemiologic evidence that persons previously infected with HEV are protected during hepatitis E outbreaks. After natural infection anti-HEV IgG has been shown to persist for up to 14 years²³ and after experimental infection antibodies were detectable for up to 10 years in chimpanzees inoculated with HEV genotype 1 or 2.²¹ A major facilitator for conducting immunogenicity and vaccine efficacy studies has been the availability of a reliable, reproducible and readily available macaque model of HEV infection.

The capsid protein encoded by ORF2 of HEV is a 72 kDa protein and is a major protein in the virion. Antibody elicited in humans and experimentally infected animals against ORF2 is long lived, cross-reactive among diverse HEV genotypes and neutralizes HEV *in vitro*. Because of

its immunogenicity, ORF2 protein of HEV has been the antigen used for all vaccine studies.

Many virus proteins, HEV vaccine candidates expressed in insect cells, virus like particles and DNA vaccines have been studied in animal models.²¹ Out of these, only two vaccine candidates, baculovirus expressed 56 kDa protein (rHEV) and *E. coli* expressed HEV 239 protein have progressed to the stage of clinical evaluation.

Genotype 1 HEV recombinant protein (rHEV) vaccine, which provided protection in nonhuman primates and phase I trials was studied in phase II trial in Nepal. In this trial, 2000 anti-HEV negative-healthy adults ranging in age from 18 to 62 years, from the Nepalese Army were randomly assigned to receive either three 20 µg rHEV vaccine doses at 0, 1 and 6 months or a matched placebo; the vaccine group was followed for a median of 804 days. During the postvaccination follow-up period from 2 weeks after the last vaccine dose until the end of study (2 years), hepatitis E developed in 66 of 896 (7.4%) individuals in the placebo group compared to 3 of 898 (0.3%) in the vaccine group. Analysis of postvaccination anti-HEV responses in a randomly selected immunogenicity subgroup (80 subjects from the vaccine group and 160 subjects from placebo group) showed 81.3 percent of those who received the vaccine had an anti-HEV level of at least 20 Walter Reed (WR) antibody units/ml one month after the second vaccine dose and 100 percent achieved this level after the third vaccine dose. However, by the end of the study, the proportion of anti-HEV positive vaccinees declined to 56.3 percent. In contrast, in the placebo group the proportion of subjects with an anti-HEV level of 20 WR U/ml or more increased to 10.6 percent reflecting the background rate of infection. Overall, the vaccine was safe and achieved efficacy rates of 87.5 percent, 85.7 percent and 95.5 percent after the first, second and third doses, respectively. The proportion of subjects with adverse events was similar in the two study groups, except that injection-site pain was increased in the vaccine group ($P = 0.03$).²⁴ The results of this vaccine trial demonstrated that the rHEV vaccine could prevent clinically overt HEV infection. Unfortunately, no further progress on the development of this vaccine has been reported.

HEV 239 vaccine is a bacterially expressed recombinant peptide encompassing 368 to 606 AA of ORF2 of HEV genotype 1 Chinese strain and it is a particulate vaccine, consisting of 23-nm virus-like particles (VLPs) which are recognized by a panel of HEV specific murine monoclonal antibodies including two neutralizing antibodies. After its success in Phase II trials, this vaccine was studied in a large randomized, double blind placebo controlled phase III trial in Jiangsu province, China. Healthy adults aged 16–65 years were randomly assigned in a 1:1 ratio to receive three doses of HEV 239 (30 µg of purified recombinant hepatitis E antigen adsorbed to aluminium hydroxide) or placebo (hepatitis B vaccine) given intramuscularly

at 0, 1, and 6 months. Participants were followed up for 19 months. The primary endpoint was prevention of hepatitis E during 12 months from the 31st day after the third dose. Analysis was based on participants who received all three doses per protocol. All participants received at least one dose of the vaccine or placebo; of the 97,356 participants, who received all the three doses, 48,693 received the HEV 239 vaccine and 48,663 received the placebo. The vaccine was tolerated well and no vaccine-related adverse events were observed in a randomly selected reactogenicity subset of participants. During the 12 months after 30 days from receipt of the third dose 15 per-protocol participants in the placebo group developed hepatitis E compared with none in the vaccine group. Vaccine efficacy after three doses was 100.0 percent (95% CI 72.1–100.0). The protective efficacy of the vaccine was 95.5 percent after the first vaccine dose and 100 percent after the second or the third vaccine dose. No vaccination-related serious adverse event was noted. The levels of anti-HEV IgG antibodies elicited by vaccination were quantified in 11,165 participants in the immunogenicity subgroup. Of the 5567 participants in the vaccine group, 98.7 percent had a four times or more increase over baseline in IgG anti-HEV concentrations one month after the third vaccine dose. In contrast, only 2.1 percent of 5598 participants in the placebo group seroconverted during the same period.²²

Despite its several limitations, which include lack of data on the duration of protection afforded by the vaccine, safety and efficacy in younger age groups, pregnant women, and patients with chronic liver disease and immune disorders, the successful Phase III trial of HEV 239 vaccine is a major leap forward in the development of a vaccine against hepatitis E.

OTHER VACCINES

Many newer vaccines are under development; however, most of these are studied in animal models only. A viral-like particle (VLP) based vaccine has been studied against Epstein-Barr virus (EBV) infection. EBV is a ubiquitous human herpes virus, which can lead to infectious mononucleosis and different cancers. In immunocompromised individuals this virus is a major cause for morbidity and mortality. Transplant recipients who did not encounter EBV prior to immunosuppression frequently develop EBV-associated malignancies but a prophylactic EBV vaccination might reduce this risk considerably. Virus-like particles (VLPs) mimic the structure of the parental virus but lack the viral genome. Therefore, VLPs are considered safe and efficient vaccine candidates. A dedicated producer cell line for EBV-derived VLPs has been prepared which contains genetically modified EBV genome devoid of all potential viral oncogenes but provides viral proteins essential for the assembly and release of VLPs. Human B cells readily take up EBV-based VLPs and present viral

epitopes in association with HLA molecules to T cells. Consequently, EBV-based VLPs are highly immunogenic and elicit humoral and strong CD8(+) and CD4(+) T cell responses *in vitro* and in a preclinical murine model *in vivo*. These findings suggest that VLP formulations might be attractive candidates to develop a safe and effective polyvalent vaccine against EBV.²⁵

Similarly, severe acute respiratory syndrome (SARS) vaccine is also undergoing initial trials. SARS caused thousands of human infections worldwide and hundreds of deaths in just a few months. Evidence indicates that SARS coronavirus (SARS-CoV) has been circulating from animals to humans since before the 2002-2003 outbreak suggesting that another pandemic may occur. This possibility has focused continuous action on SARS vaccine research. Inactivated vaccines, viral and bacterial vector vaccines, recombinant protein vaccines, subunit vaccines, DNA vaccines, and live-attenuated virus vaccines have been studied in different animal models. While there is much evidence that various vaccine strategies against SARS are safe and immunogenic, vaccinated animals still display significant disease upon challenge.²⁶ Current data suggest that intranasal vaccination may be crucial and that new or combination strategies may be required for good protective efficacy against SARS in humans. Moreover, potential vaccine enhancement of SARS has also been shown in some studies.²⁷

Vaccines against hepatitis C, cytomegalovirus, herpes simplex, respiratory syncytial virus, diarrheal diseases, parasitic infections and bacterial diseases (*Staphylococcus* and *Streptococcus*) are also under studies.

Older Vaccines Revisited

Sanjay Srirampur, Pritesh Nagar

INTRODUCTION

The Expanded Program of Immunization (EPI) was introduced in our country in the year 1978 with an aim to cover 6 childhood diseases.¹ In 1985 measles immunization was added to the EPI and thus the Universal Immunization Program (UIP) came into existence (Typhoid was dropped from the schedule in 1981).^{1,2} The UIP coverage includes BCG, DPT, OPV and measles. From then on till 2011 vaccines and vaccination programs have progressed by leaps and bounds. CDC and IAP regularly issue newer schedules for vaccination based on the available evidence and disease burden.^{1,3} However, at the national and public health sector level, introduction of newer vaccines has not made much progress since 1985 (with the exception of Hepatitis B and Hib in select districts).¹ This chapter cannot cover all aspects of immunization and the IAP 2011 guidebook is an ideal option for that. Here we intend to rediscover these old vaccines from a bygone era and highlight their relevance and importance in the 21st century.

BACILLUS CALMETTE-GUÉRIN (BCG)

The last publication of Advisory Committee on Immunization Practices (ACIPs) on BCG was in 1996.⁴ This tells about the lost importance of this vaccine in the developed nations; where the incidence of the disease is very low. The situation in India is however different. In addition to the highest prevalence of the disease in the world; the HIV pandemic is adding further to the disease burden in India.^{5,6}

The *Bacillus Calmette-Guérin* (BCG) vaccine was introduced in 1921 and till today is the only one available to prevent tuberculosis.⁶⁻⁸ The current vaccine strains are all descendants of the original *M. bovis* isolate that Calmette and Guérin passaged through numerous cycles during the 13-year period 1909 to 1921. Subsequent passages

under different laboratory conditions resulted in a variety of new BCG strains showing phenotypic as well as genotypic differences.⁵ After about a century of use, BCG still remains controversial with known variations in vaccine strains and efficacy.⁶ While most experts agree that BCG is efficacious against severe forms of childhood tuberculosis, its efficacy in adults is highly variable.^{5,9} It does not prevent the establishment of primary disease or reactivation of latent disease.⁵ As a result of the uncertain efficacy of the BCG vaccine, countries have developed very different BCG vaccination policies. Some countries, such as the United Kingdom, have or have had universal BCG vaccination programs, while others (including Canada and the United States) either only recommended BCG for high-risk groups or did not advocate BCG countrywide.⁶ India adopts a policy of universal immunization with BCG at birth. Regular boosters are currently not recommended in our country (16 countries have adopted the policy of BCG boosters).^{1,2,6} For details on individual country's policies "The World BCG Atlas" (available at www.bcgatlas.org) is an excellent source of information.

BCG Vaccination Policies

Clinicians cannot keep a track of BCG vaccination policies across all countries and most adult immigrants do not remember their/retain their childhood immunization records. The BCG world atlas is the only known comprehensive source of information on BCG vaccination across countries and over time.⁶ Most of the countries across the world have begun their BCG vaccination in between 1940 and 80. Currently nine countries have ceased universal immunization with BCG.⁶ Sixteen countries adopt the policy of BCG booster routinely and four out of these use two boosters after the initial dose.⁶ Eight countries routinely employ TST (tuberculin skin testing) after BCG

vaccination. The BCG coverage across the world is in the range of 70 to 100 percent.⁶

WHO Position Paper^{5,10}

- Countries with high burden of the disease should adopt the policy of universal BCG vaccination.
- Countries with a low burden of tuberculosis can choose to limit the vaccination to high risk groups.
- BCG vaccination is not routinely recommended for adults. Vaccination may be considered for those adults who are tuberculin negative and are in (unavoidable) close contact with a multidrug tuberculosis case.
- Repeat vaccination with BCG has no proven benefit.
- For Infants of HIV positive mothers WHO made these new recommendations in 2007:
 - a. For infants whose HIV status is unknown and show no clinical signs/ symptoms of HIV infection – BCG vaccination is recommended.
 - b. Infants who are HIV positive with or without clinical signs/ symptoms – BCG vaccination is not recommended.
 - c. For infants with clinical signs/ symptoms but unknown HIV status – BCG vaccination is not recommended. This applies only to infants who have not received BCG soon after birth; because HIV symptoms usually appear after 3 months.

IAP Recommendations¹

- IAP recommends routine vaccination with BCG at birth or six weeks (if birth dose is missed).
- Children till the age of 5 years can receive catch up vaccination.
- For a child who does not demonstrate a BCG scar; a second dose of BCG can be given till the age of 5 years.
- TST is not recommended at any stage.

POLIO VACCINES

As on October 5th 2011, 1002 cases of polio have been reported worldwide in past 12 months and about 290 in past 6 months (WHO data as on 5th October 2011).¹¹ This year only one case of (wild polio virus – WPV 1) was reported from India on 13th January 2011 from West Bengal (WHO data as on 5th October 2011).¹¹ There is a 40 percent decline in the number of polio cases this year compared to last year. Two effective polio vaccines are available for the past five decades – Salk inactivated polio vaccine (IPV) and sabin oral polio vaccine (OPV). The global polio eradication program was launched in 1988 and today only 4 countries—India, Pakistan, Afghanistan and Nigeria are polio endemic.^{1,11} WPV2 has been last isolated in 1999.^{1,11} In the year 2005 two new monovalent polio vaccines – mOPV1 and mOPV3 were introduced to enhance the supplementary immunization activities.¹

Polio Vaccination Policies

The last case of wild polio in the Americas and western hemisphere was isolated in 1991 and 1994 respectively^{12,13} with the use of OPV alone. The US shifted from an all OPV schedule to sequential IPV-OPV schedule in 1997 and from the year 2000 an all IPV schedule is in force.^{12,14} Many of the industrialized nations also have done the same. This is done to eliminate the burden of vaccine associated paralytic poliomyelitis (VAPP); a rare adverse event of OPV. The ACIP recommends a 4-dose schedule for IPV. These should be administered at 2 months, 4 months, 6 to 18 months and 4 to 6 years.¹⁵ The final dose of IPV should be administered after the age of 4 years regardless the number of previous doses.¹⁵ If a child is being immunized with DTaP-IPV/Hib combination vaccine at 2, 4, 6 and 15 to 18 months; then an additional booster dose of IPV/ IPV containing vaccine is needed at 4 to 6 years. This leads to a 5-dose schedule for IPV and is recommended by ACIP.¹⁵ This is quite different from the IAP recommendations which will be discussed later.

WHO Position Paper¹⁶

- OPV is highly heat sensitive vaccine and must be kept frozen or, after thawing it should be kept at temperatures of 2 to 8°C for a maximum of 6 months.
- OPV is the vaccine of choice for Global Polio Eradication Program. It has eradicated WPV2 from the world and eliminated WPV1 and WPV3 in 3 of 6 WHO regions.
- OPV alone along with birth dose is recommended for all polio endemic countries and in countries at high risk for importation of the disease.
- OPV alone preferably with birth dose is recommended for all countries with a moderate to high potential for transmission and importation of WPV.
- In countries with a high risk for importation of WPV, sequential IPV-OPV should be introduced only after immunization coverage is more than 95 percent. Initial 2 doses of IPV should be followed ≥2 doses of OPV to ensure sufficient level of protection in the intestinal mucosa and a decrease in the incidence of VAPP.
- IPV alone may be considered in countries with a very low risk of WPV importation and transmission. IPV alone is not an economically feasible option in the pre-eradication era.
- WHO recommends 3 doses of primary series of OPV at 6, 10 and 14 weeks or 2, 4, and 6 months
- When sequential IPV-OPV is used, IPV-OPV-OPV or IPV-IPV-OPV-OPV schedule is recommended in the primary series.
- Previously immunized persons travelling to polio endemic countries should be offered a single dose of polio vaccine before the journey.

The above recommendations were published in 2010 and pertain to polio vaccination in the pre-eradication era. In 2006 WHO had suggested methods to be adopted in post polio eradication era. A review of the same is due. According to the 2006 recommendations countries will have 2 options after polio eradication and OPV cessation – either to stop all polio vaccination or shift to an all IPV schedule.¹⁷ OPV alone or in combination is not an option in posteradication era, as it may lead to re-establishment of the disease.¹⁷

IAP Recommendations¹

- The IAPCOI recommends OPV at birth, 3 dose primary series and boosters at 15 to 18 months and 4 to 6 years. In addition OPV is recommended on all NIDs and SNIDs
- IPV should be offered to all children in addition to OPV at 6, 10, 14 weeks and a booster at 15 to 18 months. An alternative option is to schedule the first 2 doses after 2 months of age, with an interval of 8 weeks between the 2 doses. This reduces the total number of IPV doses required to 3.
- IPV can be offered as catch up vaccination for children up to 5 years of age in the form of 2 doses 8 weeks apart.
- Unlike the ACIP recommendations, a 5th year booster of IPV is not included; only OPV is indicated at 4 to 6 years.

DIPHTHERIA, TETANUS AND PERTUSSIS VACCINES

Vaccination with DPT had begun as early as the 1940's in certain parts of the world.¹⁸ Currently a wide variety of DPT, alone and in combination are available. These are: 1. DTwP (whole cell pertussis) 2. DTaP (acellular pertussis) 3. Tdap (for 10th year booster) 4. DT and 5. dT. The immunogenicity and efficacy for diphtheria and tetanus exceeds 95 percent after 3 doses. Protection against pertussis is lower; in the range of 61 to 89 percent with whole cell vaccines.^{19,20} The acellular pertussis vaccines have efficacy rates that approach the best whole vaccines.²¹ However, among the acellular vaccines, the multi-component acellular vaccines have higher protective efficacy than the 1 and 2 component vaccines.²¹ There are no safety concerns for whole cell vaccines and the WHO position paper acknowledges this as well. The only absolute contraindications for pertussis vaccination (whole cell and acellular) are anaphylaxis and encephalopathy (not attributable to any cause) within 7 days of vaccination.²²

DPT Vaccination Policies

ACIP had proposed the routine use of DTaP for United States in 1997.²² The recommendation is 5 doses in a primary series at 2, 4 and 6 months and boosters at 15 to 18 months and 4 to 6 years.²² At that point the

recommendation for the 10th year booster was the use of Td. With the availability of reduced diphtheria toxoid and acellular pertussis vaccines (Tdap), ACIP recommended the use of these for the 10th year booster and as catch up vaccination after 7 years age.²³ This was done to curb the rising incidence of pertussis among adolescents and adults. A year later in 2006 ACIP came out with recommendations for adults. In a nutshell adults aged 19 to 64 years should receive one dose of Tdap to protect against pertussis in addition to the other 2 diseases.²⁴ Tdap is also recommended in health care personnel and pregnant women (during postpartum period).^{24,25} Postpartum women should receive one dose of Tdap before discharge from hospital, if 2 or more doses have elapsed since the last dose of Td. ACIP recommends vaccination with Td during pregnancy if 10 or more years have elapsed since the last booster. If the mother has sufficient protection against tetanus, then Td can be substituted with Tdap during immediate postpartum period. Further details on this can be found in the 2008 ACIP publication on this matter.²⁶ Currently there is no data on safety of Tdap in pregnancy. In special circumstances where there is high risk of pertussis Tdap may be given during 2nd or 3rd trimester after informed consent.²⁶ An April 2011 provisional recommendation from ACIP suggests the use of a single dose of Tdap among health care workers (if not received previously) irrespective of the previous dose of Td.²⁷

WHO Position Paper²⁸⁻³⁰

- Vaccination with DPT should begin with a primary series of 3 doses during infancy with 1 to 2 boosters by the age of 4 to 7 years.
- For children 1 to 7 years of age who are not previously immunized, 2 doses 2 months apart followed by a booster 6 to 12 months later is recommended.
- After 7 years of age Td should be used for vaccination. If feasible Tdap should be used instead of Td.
- Pregnant women who have received complete childhood immunization should receive at least 1 dose of Td during the first pregnancy. If the childhood immunization schedule is incomplete then 2 doses at least 4 weeks apart are recommended.
- WHO does not differentiate between wP and aP for national immunization programs. In resource poor settings it recommends the use of wP as the vaccine of choice.
- WHO Position paper believes that there is insufficient evidence to recommend routine use of pertussis containing vaccines for adolescents and adults. This schedule can prevent pertussis in the above mentioned age groups, but has little impact on pertussis in infancy – where the morbidity is highest. Hence, WHO recommends that a high coverage of primary immunization should be the first priority followed by the two boosters.

- Only vaccines containing aP should be used after 6 years.
- Similar to ACIP, WHO finds that there is insufficient evidence to recommend the vaccination of pregnant women with pertussis containing vaccines
- If the economics and logistics permit, WHO recommends the vaccination of health care workers with pertussis containing vaccines.

IAP Recommendations¹

- IAPCOI universally endorses the use of wP containing vaccines.
- Three doses at 6, 10, and 14 weeks followed by boosters at 15 to 18 months and 4 to 6 years is recommended.
- Catch immunization schedule is similar to the WHO recommendation.
- IAPCOI suggests the use of Td as the 10th year booster; catch up vaccination after 7 years and in all situations where TT is used.
- IAP recommends the use of Tdap for 10th year booster for those who can afford the vaccine. In addition IAP also endorses most of the recommendations suggested for Tdap by ACIP.
- After 7 years catch up vaccination can be done with one dose of Tdap followed by 2 doses of Td.

MEASLES

Measles is a disease that occurs only in humans and is transmitted by respiratory droplets. With the absence of an intermediary host; measles has generated a lot of interest for a potential eradication. Hence, the measles vaccination garners a lot of importance at the national and international level. Maternal antibodies provide protection for the first 6 to 9 months of infancy. A number of live attenuated vaccines are available against measles either as monovalent measles vaccine or measles containing vaccine (MCV). The MCVs are MMR (measles, mumps and rubella) and MMRV (measles, mumps, rubella and varicella).³¹ Most measles vaccines are derivatives of the original Edmonston strain, isolated in 1954 by Enders and Peebles.³² Strains derived from this include the Schwarz, Edmonston – Zagreb, AIK-C and Moraten strains. Nucleotide sequence analysis has not revealed much of a difference between these strains. The vaccines underwent trials in 1958 and were licensed for human use in 1963.^{32,33}

Measles Vaccination Policies

Measles vaccination was introduced in the US in 1963 and in 1993 transmission of indigenous measles transmission was interrupted completely.³² By 1989 the US had already adopted the policy of 2 doses of measles in the form of MMR. The 2nd dose was initially planned at 11 to 12 years; but later the age was brought down to 4 to 6 years.³³ The Enders-Edmonston strain, grown in chick embryo

fibroblast culture is the only vaccine available in the US.³⁴ The idea of 2 doses in measles vaccination is different from other vaccines. The second dose is not a booster dose. It is given so that persons who do not respond to first dose of measles vaccine will mount an immune response after second dose.³⁵ All people born after 1957 should receive at least one on dose of MMR. All women of childbearing age should receive one dose of MMR unless contraindicated (This is for protection against Rubella).³⁴ HIV infected children who are not severely immunocompromised should receive first dose of MMR soon after 1st birthday and 2nd dose after 28 days.^{34,36} Those children at risk for measles should receive one dose of measles vaccine at 6 to 12 months followed by the earlier mentioned schedule of MMR.^{34,36} In infants >6 months age measles vaccine can be used as post exposure prophylaxis within 72 hours of exposure.³⁴

WHO Position Paper³¹

Like the wild measles virus, measles vaccine causes both a stimulating and suppressing effect on the immune system. This suppressing effect is harmless generally, but forms the basis for not giving BCG with measles (for those who did not receive BCG earlier). The median percentage of children, who seroconverted after 1st dose of measles vaccine at 8 to 9 months, was 89.6 percent when compared to 99 percent of those at 11 to 12 months. Vaccination before 6 months fails to produce seroconversion due to immaturity of immune system as well as neutralizing maternal antibodies.³⁷

- Measles vaccines are safe, effective, inexpensive and provide long lasting immunity. Hence, all countries should aim at providing 2 doses of measles vaccine in their immunization programs.
- Countries aiming at control of measles and reducing mortality should aim at ≥ 90 percent measles coverage. Vaccination coverage of ≥ 95 percent for both the doses of measles vaccines helps in achieving elimination of measles.
- In areas with high measles transmission, the first dose of measles/MCV should be administered at 9 months. All unvaccinated children after 9 months should receive their vaccine as soon as possible. In countries with low risk of measles transmission, the first dose may be administered at 12 months.
- MCV2 should be added to national immunization schedule after ≥ 80 percent coverage with MCV1 is achieved. Till then countries should concentrate on improving MCV1 coverage and conduct supplementary immunization activities (SIAs). However, there are situations under which a country may choose to introduce MCV2 without satisfying the above criteria. The details of this can be found in the WHO position paper.

- The optimal timing of 2nd dose of measles is 15 to 18 months. However, it can be given any time 1 month after the first dose.
- Measles vaccination should be offered to children with HIV infection. The WHO recommendation is similar to the ACIP recommendations mentioned earlier.

IAP Recommendations¹

Even after 5 decades of availability and 2 to ½ decades of UIP measles coverage is around 71 percent in our country. Indian measles vaccines are usually made from the Edmonston-Zagreb strain grown on human diploid cells or chick embryo cells.

- IAP recommends the first dose of measles vaccine at 9 months age. In the event of an outbreak the first dose may given as early as 6 months.
- A second dose of measles vaccine, preferably MMR should be introduced in UIP at 18 months age for states with >80 percent coverage with 1st dose of measles vaccine.
- For states with <80 percent coverage SIA should be optimized to reduce mortality from measles.
- In addition IAP recommends 2 doses of MMR at 12 to 15 months and 4 to 6 years. The second dose of MMR is to protect those who fail seroconversion against mumps, and less commonly rubella, with the first dose of the vaccine.

CONCLUSION

There are several vaccines which may now be called as older ones; like HIB, Hepatitis B and MMR to name a few. However, this chapter was mainly intended to cover the oldest of the lot; those vaccines that were introduced in 1985 and even before that. The UIP has not undergone any major changes from its inception. In 2006 Hepatitis B, second dose of measles and Japanese B encephalitis have been introduced into UIP.³⁸ The implementation is occurring in a phased manner. Though a significant dent has been made to the mortality caused by the vaccine preventable diseases, a lot more needs to be achieved. The UIP coverage in India is >70 percent in only 11 states, 50 to 70 percent in 13 states and <50 percent in the remaining states.³⁸ These remaining states are the most populous states and they bring overall national average to less than 50 percent.³⁸ There are several bottle necks preventing high immunization coverage. Weak surveillance system, lack of epidemiological data, limited economics and lack of trained manpower are just a few of them. The government with the help of NTAGI (National Technical Advisory Group of Immunization) and other organizations is aiming to improve the existing UIP and make immunization of all children of our country a dream come true.

Suresh Gupta

INTRODUCTION

Rabies is a major public health problem throughout the world and more so in the Africa and Asia. It is a zoonotic disease caused by RNA viruses in the family Rhabdoviridae, genus *Lyssavirus*. It is invariably fatal once it occurs and has mortality rate of almost 100 percent. Rabies virus is transmitted in the saliva of rabid mammals via a bite. After entry to the central nervous system, these viruses cause an acute, progressive encephalomyelitis. The incubation period usually ranges from 1 to 3 months after exposure, but can range from days to years. Rabies can be prevented by avoidance of viral exposure and initiation of prompt medical intervention when exposure does occur. As a part of its mandate to provide guidance, World Health Organization (WHO) issues a series of regularly updated position papers on vaccines against diseases that have an international public health impact. In August 2010, WHO published a position paper on rabies vaccines, which incorporates the most recent developments in the field of human rabies vaccines, in particular with regard to immunization schedules.¹ The current position paper replaces the previous position paper on rabies vaccines published in the weekly epidemiological record in December 2007 by WHO. The following article is based on this position paper and discusses strategies to prevent infection with rabies after being bitten or exposed to an infected animal or suspected animal.

EPIDEMIOLOGY

Rabies is a viral zoonosis that is widely distributed across the globe in >100 countries and territories. Rabies infects domestic and wild animals and spreads to the human through close contact with infected saliva. More than 95 percent of human rabies infections come from dogs. At the global level, ≥ 15 million people receive rabies

prophylaxis annually, the majority of them live in China and India. Rabies is almost invariably fatal, once clinical symptoms have developed. In a number of countries, deaths due to rabies are under-reported. The most of the estimated 55,000 deaths caused by rabies each year occur in rural areas of Africa and Asia. In India alone 20,000 deaths (that is, about 2/1,00,000 population at risk) are estimated to occur annually. Although all age groups are susceptible, rabies is most common in children aged <15 years; on average 40 percent of postexposure immunizations are given to children aged 5 to 14 years, and the majority of those immunized are males.^{2,3}

In industrialized countries, human rabies is close to being eliminated owing to the vaccination of domestic dogs and the implementation of other control measures. In Thailand also the mass vaccination of dogs and widespread immunization of humans following exposure have significantly reduced the number of human rabies deaths.

RABIES

Virology

The rabies virus (RABV) belongs to the genus *Lyssa* virus in the family Rhabdoviridae. There are 11 species classified under *Lyssa* virus genus and all are known to cause progressive human encephalitis. The RABV is the major representative and its RNA encodes 5 proteins, including the G glycoprotein that carries the main antigenic sites.

Transmission

Human infection usually occurs following a transdermal bite or scratch by an infected animal. The other mode of transmission is person's mucosa or fresh skin wounds coming in contact with infected saliva. Human-to-human transmission by bite is extremely uncommon except for

transplantation of an infected organ. Ingestion of raw meat or other tissues from animals infected with rabies is not a known source of human infection. The incubation period depends upon the amount of virus inoculated, the degree of innervation at the site of viral entry and the proximity of the bite to the central nervous system (CNS). The typical incubation period is 1 to 3 months but may vary from <1 week to >1 year. Inoculated virus is transported to the CNS via the peripheral nerves. In brain, it multiplies and disseminates rapidly, again via the nervous system to many different tissues including the salivary glands and resulting in progressive fatal encephalomyelitis.

Diagnosis

Almost 60 to 70 percent will have furious rabies characterized by hyperactivity and fluctuating consciousness, hydrophobia or aerophobia, or both and resulting in death in few days due to cardiorespiratory arrest. Paralytic rabies represents as much as 30 percent of human cases and has a less dramatic and longer course often misdiagnosed and under-reported. The paralytic form of rabies is often misdiagnosed and this contributes to the under-reporting of the disease. No tests are available to diagnose rabies infection in humans before the onset of clinical disease. At the stage of clinical manifestations, saliva, urine, extracted hair follicles and CSF may be tested by virus isolation or by polymerase chain reaction, and serum or CSF may be tested for antibodies to rabies virus. Skin biopsy specimens or postmortem brain biopsy may be examined for rabies antigen fluorescent antibody test or a direct rapid immune-histochemical test. A rapid tissue culture isolation test may also be used.

Note: Rabies differs from many other infections in that the development of clinical disease can be prevented through timely immunization even after exposure to the infecting agent.

RABIES VACCINES

Since their development more than four decades ago, concentrated and purified cell-culture and embryonated egg based rabies vaccines (here jointly referred to as CCVs) have proved to be safe and effective in preventing rabies. These vaccines are intended for pre-exposure prophylaxis as well as post-exposure prophylaxis, and have been administered to millions of people worldwide. Some countries in Asia and Latin America still depend partially on rabies vaccines derived from animal nerve tissues for postexposure prophylaxis. The production and use of nerve tissue vaccines is not recommended by WHO due to severe side effects and less immunogenicity.³ CCVs consist of rabies virus that has been propagated in cell substrates such as human diploid cells (embryonic fibroblast cells), fetal rhesus diploid cells, vero cells (kidney cells from

the African green monkey), primary Syrian hamster kidney cells, primary chick embryo cells or in embryonated duck eggs.⁴ The more recently developed vaccines based on chick embryo cells and vero cells have safety and efficacy records comparable to those of the human diploid cell vaccines and are less expensive. No rabies vaccines are supplied in multidose vials for intramuscular injection. Rabies vaccines prequalified by WHO do not contain preservatives such as thimerosal. The shelf-life of these vaccines is ≥ 3 years, provided they are stored at $+2^{\circ}\text{C}$ to $+8^{\circ}\text{C}$ and protected from sunlight. Following reconstitution with the accompanying sterile diluent, the vaccines should be used immediately, or within 6 to 8 hours if kept at the correct temperature. All CCVs should comply with the WHO recommended potency of ≥ 2.5 IU per single intramuscular dose. (0.5 ml or 1.0 ml volume after reconstitution, depending on the type of vaccine).

Intramuscular and Intradermal Administration

The cost of CCVs for intramuscular administration limits their widespread use in many areas where canine rabies is prevalent. Intradermal administration of these vaccines offers an equally safe and immunogenic alternative that requires only 1 to 2 vials of vaccine to complete a full course of postexposure prophylaxis, thereby reducing the volume used and the direct cost of vaccine by 60 to 80 percent compared with standard intramuscular vaccination.⁵ There is no evidence that intradermal administration requires vaccines with potency higher than that recommended for intramuscularly-administered rabies vaccines.^{6,7} Intradermal regimens have been successfully introduced for postexposure prophylaxis in countries such as India, the Philippines, Sri Lanka and Thailand.⁵ Intradermal regimens require sufficient trained staff to ensure correct storage, reconstitution and injection.

Vaccine Efficacy and Immunogenicity

Rabies is a fatal disease. Therefore, randomized controlled human trials involving untreated comparison groups cannot be carried out for ethical reasons. Direct assessment of vaccine-induced protection is based on the efficacy of post-exposure prophylaxis following category II or III exposure to animals confirmed to be rabid through laboratory analysis. The efficacy of vaccine can be also made indirectly through immunogenicity studies. All CCVs induce a prompt and high rabies-virus neutralizing antibody response to the viral G protein. WHO's specified minimum titer of 0.5 IU/ml of serum, measured by the rapid fluorescent focus inhibition test (RFFIT) or the fluorescent antibody virus neutralization test (FAVN) is a widely used reference. In healthy vaccines, this level should be achieved in most individuals by day 14 of a post-exposure regimen, with or without simultaneous administration of rabies immunoglobulin and irrespective of age.

When new rabies vaccines are introduced, their immunogenicity is evaluated by comparing the rabies-virus neutralizing antibody titers induced by the vaccine being tested with those induced by a vaccine of demonstrated efficacy. Studies from Thailand and several other countries in South-East Asia have established the immunogenicity and effectiveness of CCVs for both pre-exposure and post-exposure prophylaxis. The feasibility of using them either intramuscularly or intradermally in all age groups, including infants, has been clearly demonstrated. In both pre-exposure and postexposure use, these vaccines induce an adequate antibody response in almost all individuals. Prompt postexposure use of CCVs combined with proper wound management and simultaneous administration of rabies immunoglobulin is almost invariably effective in preventing rabies. However, delays in starting or incomplete prophylaxis may result in failure, particularly following bites in highly innervated regions, such as the head, neck or hands or following multiple wounds.

Duration of Immunity

The development of immunological memory after vaccination with CCVs is critical for the establishment of long lasting immunity against rabies in humans. Individuals who had received their primary series 5 to 21 years previously showed good anamnestic responses after booster vaccination. Long-term immunity is also achieved with intradermal immunization and may persist even when antibodies are no longer detectable. The anamnestic response to a booster vaccination is seen with both *pre* as well as postexposure prophylaxis.

Adverse Events Following Immunization

In general, CCVs have been shown to be safe and well tolerated. However, in 35 to 45 percent of vaccinees, minor and transient erythema, pain and/ or swelling may occur at the site of injection, particularly following intradermal administration of a booster. Mild systemic adverse events following immunization (AEFI), such as transient fever, headache, dizziness and gastrointestinal symptoms, have been observed in 5 to 15 percent of vaccinees. Serious AEFIs mainly of allergic or neurological nature rarely occur.⁸

Contraindications and Precautions

For pre-exposure prophylaxis, previous severe reaction to any components of the vaccine is a contraindication to further use of the same vaccine. Because rabies is a lethal disease, no contraindications exist to postexposure prophylaxis following high-risk exposure. This is also the case for postexposure prophylaxis during infancy or pregnancy and for immunocompromised individuals, including children with HIV/AIDS. People taking chloroquine for malaria treatment or prophylaxis may have a reduced

response to intradermal rabies vaccination. These patients should receive the vaccine intramuscularly. As with all other immunizations, vaccinees should if possible be kept under medical supervision for at least 15 to 20 minutes following vaccination.

Replacing Nerve-tissue Vaccines with CCVs

With time, the CCVs have become more affordable particularly with intradermal administration schedules. But still some of the Asian and Latin American countries are producing and using nerve-tissue vaccines. These vaccines induce more-severe adverse reactions and are less immunogenic than CCVs. It is therefore imperative that production and use of nerve-tissue vaccines be discontinued as soon as possible and replaced with CCVs.

Intradermal Administration of CCVs

For administration by the intradermal route, CCVs should meet the same WHO requirements for production and control as required for rabies vaccines delivered intramuscularly. In addition, the immunogenicity and safety of intradermally administered vaccines should be demonstrated in appropriate clinical trials using the WHO recommended postexposure prophylaxis regimen and a volume of 0.1 ml per intradermal site.⁶ New postexposure regimens, particularly those using intradermal administration, even if shown to be safe and efficacious, must have clear practical or economical advantages, or both, over existing regimens if they are to be endorsed. In countries where intradermal administration is an approved route for postexposure prophylaxis, manufacturers of vaccines proved to be safe and efficacious by this route should be requested to state that their vaccine can be used intradermally.

RABIES IMMUNOGLOBULIN

Rabies immunoglobulin should be administered in all people with category III exposure and to those with category II exposure who are immunodeficient. Human rabies immunoglobulin has a relatively slow clearance (the half-life is about 21 days), so it is the preferred product, particularly in cases of multiple severe exposures and bites on the head, face and hands. However, human rabies immunoglobulin is in short supply and available mainly in industrialized countries. Where it is not available or affordable, equine immunoglobulin or F(ab')₃ products of equine immunoglobulin should be used, although the F(ab') have a faster clearance than human rabies immunoglobulin. Most of the new equine immunoglobulin preparations are potent, highly purified, safe and considerably less expensive than human rabies immunoglobulin. However, they are of heterologous origin and carry a small risk of anaphylactic reaction (1/45 000 cases). There are no scientific

grounds for performing a skin test prior to administering equine immunoglobulin because testing does not predict reactions, and it should be given whatever the result of the test. The treating physician should be prepared to manage anaphylaxis which, although rare, could occur during any stage of administration.⁹

PRE-EXPOSURE PROPHYLAXIS

Pre-exposure prophylaxis is recommended for anyone who will be at continual, frequent or increased risk of exposure to the rabies virus, either as a result of their residence or occupation (for example, laboratory workers dealing with RABV and other lyssa viruses, veterinarians and animal handlers). Travelers with extensive outdoor exposure in rural high-risk areas where immediate access to appropriate medical care may be limited should also be vaccinated regardless of duration of stay. Children living in or visiting rabies-affected areas are at particular risk. WHO encourages the implementation of carefully designed studies on the feasibility, cost-effectiveness and long-term impact of incorporating CCVs into the immunization programs of infants and children if canine rabies is a public health problem.

Intramuscular Administration for Pre-exposure Prophylaxis

Pre-exposure prophylaxis requires intramuscular doses of 1 ml or 0.5 ml (volume depending on the type of vaccine) to be given on days 0, 7 and 21 or 28. For adults and children aged ≥ 2 years, the vaccine should always be administered in the deltoid area of the arm; for children aged < 2 years, the anterolateral area of the thigh is recommended. Rabies vaccine should not be administered in the gluteal area, as the induction of an adequate immune response may be less reliable.

Intradermal Administration for Pre-exposure Prophylaxis

Intradermal administration of 0.1 ml volume on days 0, 7, and 21 or 28 is an acceptable alternative to the standard intramuscular route. To lead to significant savings, intradermal immunization sessions should involve enough individuals to utilize all opened vials within 6 to 8 hours.

Requirements for Booster Injections

Booster doses of rabies vaccines are not required for individuals living in or travelling to high-risk areas who have received a complete primary series of pre-exposure or postexposure prophylaxis with a CCV. Periodic booster injections are recommended as an extra precaution only for people with frequent occupational exposure. If available, antibody monitoring of personnel at risk is preferred to the administration of routine boosters. For people who are potentially at risk of laboratory exposure to high concentrations of live rabies virus, antibody testing should be done every 6 months. Those professionals who are not at continual risk of exposure through their activities, such as certain categories of veterinarians and animal health officers, should have serological monitoring every 2 years. Because vaccine-induced immunity persists in most cases for years, a booster would be recommended only if rabies virus neutralizing antibody titers fall to < 0.5 IU/ml.

POSTEXPOSURE PROPHYLAXIS

The indication for postexposure prophylaxis depends on the type of contact with the suspected rabid animal:

For category I exposures, no prophylaxis is required; for category II, immediate vaccination is recommended; and for category III, immediate vaccination and administration of rabies immunoglobulin are recommended. For categories II and III, thorough washing and flushing (for about 15 minutes, if possible) with soap or detergent and

Table 1: WHO definitions of categories of exposure for the use of rabies biologicals

<i>Category of exposures</i>	
Category I	Touching or feeding animals licks on intact skin (that is no exposure);
Category II	Nibbling of uncovered skin minor scratches or abrasions without bleeding;
Category III	Single or multiple transdermal bites or scratches contamination of mucous membrane with saliva from licks/ licks on broken skin; exposures to bats.
<i>Prophylaxis recommended</i>	
For category I exposures no prophylaxis is required;	
For category II immediate vaccination is recommended; and	
For category III immediate vaccination and administration of rabies immunoglobulin are recommended.	
For categories II and III thorough washing and flushing (for about 15 minutes if possible) with soap or detergent and copious amounts of water of all bite wounds and scratches should be done immediately or as early as possible.	

Table 2: Rabies postexposure prophylaxis—general considerations and wound management

- Wound management should be done immediate and is essential even if the person presents long after exposure
- It consists of immediate washing and flushing for 15 minutes with soap and water, or water alone and disinfection with ethanol (700ml/L) or iodine (tincture or aqueous solution).
- Postpone suturing if possible; in case suturing is necessary ensure that RIG has been applied locally; Apply antimicrobials and tetanus toxoid if necessary
- No contraindications if modern purified rabies vaccines are used;
- Use the vaccine regimens and routes of administration as recommended
- Initiation of PEP should not be delayed by dog observation.
- Pregnancy and infancy are not contraindications to PEP

copious amounts of water of all bite wounds and scratches should be done immediately or as early as possible. Where available an iodine-containing, or similarly viricidal, topical preparation should be applied to the wound.

When it is impossible to complete postexposure prophylaxis with the same CCV, another CCV should be used instead. However, since no study has been done yet on vaccine immunogenicity following changes in the route of vaccine administration (for example, from intramuscular to intradermal) during postexposure prophylaxis, such changes should be the exception. Postexposure prophylaxis may be discontinued if the suspect animal is proved by appropriate laboratory examination to be free of rabies or, in the case of domestic dogs, cats or ferrets, the animal remains healthy throughout a 10-day observation period starting from the date of the bite. Factors that should be taken into consideration when deciding whether to initiate postexposure prophylaxis include the epidemiological likelihood of the implicated animal being rabid, the category of exposure (I–III) and the clinical features of the animal, as well as its availability for observation and laboratory testing. In most situations in developing countries, the vaccination status of the implicated animal alone should not be considered when deciding whether to give or withhold prophylaxis.

Intramuscular Administration for Postexposure Prophylaxis

The postexposure vaccination schedule is based on injecting 1 ml or 0.5 ml (the volume depends on the type of vaccine) into the deltoid muscle (or anterolateral thigh in children aged <2 years) of patients with category II and III exposures. The recommended regimen consists of either a 5-dose or a 4-dose schedule:

- *5 Dose regimen:*
 - The 5-dose regimen prescribes 1 dose on each of days 0, 3, 7, 14 and 28.
- *4 Dose regimen*
 - The 4-dose regimen prescribes 2 doses on day 0 (1 in each of the 2 deltoid or thigh sites) followed by 1 dose on each of days 7 and 21.

- An alternative for healthy, fully immunocompetent, exposed people who receive wound care plus high quality rabies immunoglobulin plus WHO-prequalified rabies vaccines, is a postexposure regimen consisting of 4 doses administered intramuscularly on days 0, 3, 7 and 14.¹⁰

Intradermal Administration for Postexposure Prophylaxis

The 2-site regimen prescribes injection of 0.1 ml at 2 sites (deltoid and thigh) on days 0, 3, 7 and 28. This regimen may be used for people with category II and III exposures in countries where the intradermal route has been endorsed by national health authorities.

Postexposure Prophylaxis for Previously Vaccinated Individuals

For rabies-exposed patients who can document previous complete pre-exposure vaccination or complete post-exposure prophylaxis with a CCV, following schedules can be used:

- *1-site 2-day Regimen:* 1 dose delivered intramuscularly or intradermally on days 0 and 3 is sufficient. Rabies immunoglobulin is not indicated in such cases. This 1-site 2-day intradermal or intramuscular regimen also applies to people vaccinated against rabies who have demonstrated rabies-virus neutralizing antibody titers of ≥ 0.5 IU/ml.
- *Single-visit-4-site Regimen:* The patient may be offered a single-visit 4-site intradermal regimen consisting of 4 injections of 0.1 ml equally distributed over left and right deltoids or prescapular areas. Vaccination cards recording previous immunizations are invaluable for making correct decisions.

Immunization of Immunocompromised Individuals

In immunocompromised individuals including patients with HIV/AIDS, a complete series of 5 doses of intramuscular CCV in combination with comprehensive wound management and local infiltration with human rabies immunoglobulin is required for patients with category II and III exposures. When feasible, the rabies-virus neutralizing

antibody response should be determined 2 to 4 weeks following vaccination to assess the possible need for an additional dose of the vaccine.

Rabies Immunoglobulin for Passive Immunization

Rabies immunoglobulin for passive immunization is administered only once, preferably at, or as soon as possible after, the initiation of postexposure vaccination. Beyond the seventh day after the first dose, rabies immunoglobulin is not indicated because an active antibody response to the CCV is presumed to have occurred. The dose of human rabies immunoglobulin is 20 IU/kg body weight; for equine immunoglobulin and F(ab')³ products, it is 40 IU/kg body weight. All of the rabies immunoglobulin, or as much as anatomically possible (but avoiding possible compartment syndrome), should be administered into or around the wound site or sites. The remaining immunoglobulin, if any, should be injected intramuscularly at a site distant from the site of vaccine administration. Rabies immunoglobulin may be diluted to a volume sufficient for all wounds to be effectively and safely infiltrated.⁶

COORDINATED RABIES CONTROL

As demonstrated in industrialized countries and in most of Latin America, eliminating rabies from dog populations significantly reduces human exposure to the disease. Mass vaccination of dogs is the single most cost-effective intervention to control and eliminate canine rabies. However, successful rabies control also depends on measures such as managing the dog population, mainly by promoting responsible dog ownership; compulsory notification of rabies in humans and animals; ensuring the availability of reliable diagnostic procedures; conducting postmortem examinations to confirm the cause of death in people suspected to have been infected with rabies; and improving coordination between all public sectors involved in rabies control.¹¹

How can dog bites be prevented?

Dog bites are a largely preventable public health problem and adults and children can learn to reduce their chances of being bitten. Before bringing a dog into household, it is better to consult with a professional to learn what breeds of dogs is the best fit for household. Dogs with histories of aggression are not suitable for households with children. It is better to spend some time with a dog before buying or adopting it and use caution when bringing a dog into a household with an infant or toddler.

If a dog is brought into home, it's better to neuter the dog to reduce aggressive tendencies and not to play aggressive games with him. Teach the dog, submissive behaviors and properly socialize and train him. One should immediately seek professional advice from veterinarians if the dog develops aggressive or undesirable behaviors. To help to

prevent children from being bitten by dogs, teach them the basic safety tips like not to approach an unfamiliar dog; not to run from a dog or scream but remain motionless; roll into a ball and lie still if knocked over by a dog; avoid direct eye contact with a dog; do not disturb a dog that is sleeping, eating, or caring for puppies and if bitten, immediately report the bite to an adult.

SUMMARY

Rabies is a viral zoonosis of mammals. Rabid dogs are the dominant source of infection in humans, in whom rabies virus causes acute, progressive encephalitis that is invariably fatal. Each year, rabies causes about 55,000 human deaths, many in children living in rural areas of Asia and Africa. The disease is grossly under-reported; it is estimated that without postexposure prophylaxis about 3,27,000 persons would die from rabies in Africa and Asia each year. In industrialized countries and in most urbanized areas of Latin America human rabies is close to being eliminated owing to the vaccination of domestic dogs and the implementation of other control measures. Cell-culture-based rabies vaccines have proven to be safe and effective in preventing rabies and have been administered to millions of people worldwide. All these vaccines can be administered intramuscularly, but some are also recommended for vaccine-saving intradermal use. When used according to WHO's recommendations, neutralizing antibody concentrations of ≥ 0.5 IU/ml are achieved in practically 100 percent of healthy vaccinees and so far, no cases of rabies have been reported in individuals with such antibody concentrations. Cell-culture-based vaccines are safe and usually well tolerated although in 35 to 45 percent of vaccinees, minor and transient erythema, pain and or swelling may occur at the site of injection, particularly following intradermal administration. Mild systemic adverse events such as transient fever, headache, dizziness and gastrointestinal symptoms, have been observed in 5 to 15 percent of vaccinees.

Pre-exposure prophylaxis is recommended for anyone who will be at continual, frequent or increased risk of exposure to rabies virus, either by nature of their residence, travel or occupation. Children living in or visiting rabies-affected areas are at particular risk. The protection is long lasting (at least 10 years) and booster doses are only recommended for people whose occupation puts them at continual or frequent risk of exposure. The indication for postexposure prophylaxis depends on the type of contact with the suspected rabid animal: category I – touching or feeding animals, licks on intact skin; category II – nibbling of uncovered skin, minor scratches or abrasions without bleeding; category III – single or multiple transdermal bites or scratches, contamination of mucous membrane with saliva from licks, licks on broken skin, and exposures to bats. For category I exposures, no prophylaxis is required; for category II, immediate vaccination

is recommended; and for category III, immediate vaccination and administration of rabies immunoglobulin are recommended. The position paper provides details on various WHO-recommended schedules for intramuscular as well as intradermal pre and postexposure vaccination, the correct use of rabies immunoglobulin, as well as on other measures to be observed following possible exposure to rabies virus.

Infections in the Immunocompromised Hosts

Satyendra Katewa, Anupam Sachdeva, SP Yadav

Immunosuppressed individuals constitute one of the rare but very fragile population from the pediatric age group. The numbers of immunocompromised individuals are increasing out of the increased survival secondary to the better management in these individuals. The outcome of immunosuppressed individuals whether inherited or iatrogenic primarily depends on the timely initiation of the appropriate management steps. The discussion in this chapter is going to focus on the basic immunopathological issues, types of infection, and their early diagnostic tools and about the appropriate management strategies in these immunosuppressed individuals.

Immunity is primarily interplay between antigens and antibodies. Antigen is a live or inactivated substance (e.g. protein, polysaccharide) capable of producing an immune response while antibodies are protein molecules (immunoglobulin's) produced by B lymphocytes to help eliminate a foreign antigen. One of the primary functions of the immune system is to prevent or cure infectious diseases and the tool used to achieve this function is immunity. Immunity helps in recognizing self vs. nonself, protects from infectious disease, usually indicated by the presence of antibodies and very specific to a single organism. The immunity is primarily of two types, the innate immunity and adaptive immunity. The basic features of innate immunity are, it's the 1st line of defense and provides initial defense against infection, it's relatively non-specific, not enhanced by immunization but necessary for the establishment and enhancement of adaptive immunity. Adaptive immunity (acquired or specific immunity) develops slowly, has got a broad activity against antigens and has a high degree of specificity. It is enhanced by immunization and activity heightened by cross talk with the innate immune system via cytokines.

The specific immunity can be acquired either naturally (Active: antigens enter the body naturally, e.g. natural

infections or Passive: antibodies pass from mother to fetus via placenta) or artificially (Active: antigens are introduced in body through vaccines and they produce antibodies or Passive: preformed antibodies in immune serum are introduced into body by injection, e.g. varicella-zoster immunoglobulin). Flow chart 1 summarizes the basic functioning of immune system.

Infections in the immunocompromised differ significantly from those in the immunocompetent. They can be more serious, more often life-threatening, more difficult to diagnose and are caused by more unusual organisms. Children can be immunocompromised for a variety of reasons. Since immunocompromised host are a heterogeneous population and no stringent criteria can be laid down to define an immunocompromised host. The complete details of the immunocompromised conditions are given in Table 1. They can also be classified as primary and secondary. *Primary* disorders are genetically inherited disorders of T cell, B cell or combined, complement and phagocytic dysfunctions. *Secondary* causes of immunocompromised hosts are-HIV, malignant neoplasms, transplant recipients (solid organ transplant or bone marrow transplant), chronic liver diseases, asplenia or postsplenectomy and therapy related. Therapy related can be immunosuppressive drugs (e.g. steroids, tacrolimus, and cyclosporin, etc.), chemotherapy drugs and secondary to Radiation therapy.¹

Degree of immunosuppression depends either on the severity of underlying disease or the doses of the given immunosuppressive agents. Drug-induced immunosuppression is a dose-dependent phenomenon. These immunosuppressed patients are incapable of mounting adequate cellular and humoral immune responses to infection including typical and atypical ones. Suboptimal immune response put these patients at an increased risk of a complicated clinical course even to the common

Condition	Type of infection	Name of the etiological agents
Congenital conditions		
X-linked hyper-IgM syndrome:	Oral ulcers and perirectal abscesses	Bacterial: Mycobacterial, Salmonella Viral: CMV and Adenovirus Protozoa: <i>Entamoeba histolytica</i> , <i>Giardia</i> and <i>Cryptosporidium</i> Fungal: <i>P. jiroveci</i> (Recurrent Abscesses), <i>Cryptococcus</i>
T-cell defects	Sinopulmonary, gastrointestinal, skin and mucus membrane infections	Bacterial: <i>Mycobacterium avium-intracellulare</i> complex Viral: Herpesviruses Fungal: <i>Candida</i> and <i>P. jiroveci</i>
Chronic mucocutaneous candidiasis:	Skin and mucus membrane infections	Candidal infection
DiGeorge (velocardiofacial) syndrome:	Recurrent sinopulmonary and Gastrointestinal infections	Bacterial: <i>S. pneumoniae</i> Fungal: <i>Candida</i> species, and <i>P. jiroveci</i> Viral: CMV and HSV
Cartilage-hair Hypoplasia: Combined B and T-cell defects	Life-threatening varicella infections Failure to thrive and thrush	Varicella and other enteric virus infections MC infection is with <i>P. jiroveci</i> infection, other common are as follows: Bacterial: <i>S. pneumoniae</i> , <i>P. aeruginosa</i> , <i>Legionella pneumophila</i> , <i>L. monocytogenes</i> , <i>Nocardia</i> species, <i>Mycobacterium</i> species Viral: VZV, HSV, CMV, Epstein-Barr virus (EBV), respiratory viral infections Protozoa: <i>Toxoplasma</i> species, <i>Cryptosporidium</i> , <i>Strongyloides</i> Fungal: <i>P. jiroveci</i>
Ataxia-telangiectasia syndrome:	Severe sinopulmonary infections and bronchiectasis	Bacterial: Capsulated bacterial infections Viral: Herpes Simplex, Herpes Zoster and Uncomplicated Varicella Fungal: <i>Candida</i>
Wiskott-Aldrich syndrome:	Bacteremia and skin infections	<i>S. Pneumoniae</i> , <i>H. influenzae</i> , <i>P. jiroveci</i> , <i>Candida</i> species, CMV, HSV, EBV
X-linked lymphoproliferative syndrome: Macrophage, cytokine, and miscellaneous defects	LN and extra lymphatic organ involvement	EBV
RANTES promoter gene polymorphisms:	Sinopulmonary and gastrointestinal infections	Bacterial: Mycobacterial, <i>Salmonella</i> and <i>Listeria</i>
Toll-like receptor mutations:	Respiratory and urinary tract (Upper)	Respiratory syncytial virus infection
Phagocyte deficiency or dysfunction	Respiratory tract, neonatal sepsis and CNS infections	Bacterial: Meningococcal Respiratory syncytial virus, CMV and parainfluenza virus Fungal: <i>Aspergillus</i> Protozoa: <i>Cysticercosis</i>
	Skin, soft tissue and mucus membrane infection	Bacterial: <i>S. aureus</i> , <i>Nocardia</i> , <i>P. aeruginosa</i> , <i>Serratia</i> , streptococci, <i>Burkholderia</i> , and <i>Chromobacterium</i> species Fungal: <i>Candida</i> and <i>Aspergillus</i>
Chediak-Higashi syndrome:	Recurrent skin and mucosal infections	Infections with <i>S. aureus</i> and streptococci
Chronic granulomatous disease:	Skin, soft tissue and mucus membrane infection	Bacterial: Catalase-positive bacteria's including <i>S. aureus</i> , <i>S. Marcescens</i> , <i>Burkholderia cepacia</i> , <i>Granulibacter Bethesdensis</i> , <i>Nocardia</i> species, <i>Chromobacterium</i> species Fungal: <i>Candida</i> species, <i>Aspergillus</i> species
Hyper-IgE (Job) syndrome:	Skin, soft tissue and mucus membrane infection	Bacterial: <i>S. aureus</i> and Streptococci Fungal: <i>Candida</i> or <i>Aspergillus</i> species
Leukocyte adhesion deficiency:	Recurrent necrotic skin and soft-tissue infection, poor wound healing, delayed cord separation, gingivitis and periodontal abscesses	Bacterial: <i>P. aeruginosa</i> , <i>S. aureus</i> , <i>E. coli</i> , <i>B. Cepacia</i> , <i>Serratia</i> , <i>Klebsiella</i> and <i>Fusarium</i> Fungal: <i>Candida</i> and <i>Aspergillus</i> species
Complement deficiencies	Recurrent sinopulmonary infections	Bacterial: <i>S. Pneumoniae</i> , <i>H. influenzae</i> and <i>Neisseria</i> species
Deficiency of C1q, C1r, C1rs, C4, C2, C3, or C5-9:		
Deficiency of factor D, factor P, factor I, factor H, or properdin:	Meningococcal infection	Meningococcal infections

infections and the situation is further complicated by the atypical clinical presentation and there by delayed clinical diagnosis. Delayed clinical diagnosis also results in inadequate treatment and increased mortality and morbidity in these patients. The type of infection and the time of infection depend mainly on the present immune status of the patient and the likely immune system reconstitution time line.

Types of Infection in Immunocompromised

As such any infectious agent can complicate any immunocompromised condition but there are few trade mark infections which are commonly found in few conditions and knowing them help in the differential diagnosis of an immunocompromised child. Tables 2^{6,11,12} and 3^{12,13} gives brief details of common infectious agents in a particular condition. It is beyond the scope of the chapter to deal

Table 3: Type of infections associated with a particular acquired/iatrogenic condition^{12,13}

<i>Acquired or Iatrogenic conditions</i>		
Malnutrition	Respiratory, gastrointestinal, tuberculosis, malaria	Bacterial: Mycobacteria and atypical mycobacteria & Salmonellosis Viral: Measles, HIV Fungal: <i>P. jiroveci</i> Protozoa: <i>Plasmodium</i>
Hematologic or oncologic conditions	Almost every system can be affected but the commoner presentation are septicemia/bacteremia, line related infections, lung and gut infections	Bacterial: Coagulase-negative staphylococci, Viridans streptococci, <i>S. aureus</i> , <i>P. aeruginosa</i> , <i>S. pneumoniae</i> , <i>S. Pyogenes</i> , <i>Aeromonas</i> , <i>Mycobacteria</i> and other gram-positive and gram-negative organisms Viral: CMV, HSV, VZV, or community respiratory viruses Fungal: <i>Candida</i> , <i>Aspergillus</i> , <i>Mucor</i> , <i>Rhizopus</i> , <i>Trichosporon</i> and <i>P. jiroveci</i> Protozoa: <i>Strongyloides</i> species, <i>Toxoplasma</i> species
Neutropenia	Septicemia, line related, lung and gut infections	Bacteria: <i>E. coli</i> , <i>K. pneumoniae</i> , <i>Enterobacter</i> species, <i>Citrobacter</i> species, <i>P. aeruginosa</i> , <i>S. aureus</i> , <i>Clostridium septicum</i> , coagulase-negative staphylococci, streptococci, enterococci, anaerobes Fungal: <i>Candida</i> and <i>Aspergillus</i> and a variety of yeasts
Corticosteroid therapy	Sinopulmonary and gastrointestinal infections	Bacterial: <i>S. aureus</i> , <i>S. pneumoniae</i> , <i>Legionella</i> , <i>Listeria</i> Viral: VZV Protozoa: <i>Strongyloides</i> Fungal: <i>P. jiroveci</i> , <i>Candida</i> and <i>Nocardia</i> (now considered as fungus)
Inhaled corticosteroids	Oral thrush and community-acquired pneumonia (CAP)	<i>Candida</i> and organism causing CAP
Inhibitors of TNF- α	Reactivation of tuberculosis, CNS and gut infections	Bacterial: <i>M. tuberculosis</i> , atypical mycobacterial infections and <i>Listeria</i> Viral: HSV encephalitis Fungal: Histoplasmosis and <i>Candida</i> Protozoa: <i>Falciparum</i> malaria
Other monoclonal antibodies Eculizumab (C5 inhibitor)	Invasive meningococcal infection	Meningococcemia
Natalizumab (Inhibitor for cellular adhesion molecule α 4-integrin)	Progressive multifocal leukoencephalopathy	JC virus
Transplantations Bone marrow or hematopoietic stem cell transplant	Any organ system can be affected but the commoner presentations are septicemia, lung, gut, skin and soft tissue. (Usually the type of infection depends on the time since transplant)	Bacterial: Aerobic gram-negative rods, coagulase-negative Staphylococci, Streptococci, <i>S. aureus</i> , <i>C. difficile</i> Viral: Respiratory and enteric viruses, CMV, VZV, HSV, EBV, HHV 6 or 7, Parvovirus B19, Polyomaviruses, Rotavirus and Adenovirus Protozoa: <i>Toxoplasma</i> Fungal: <i>Candida</i> , <i>Aspergillus</i> , <i>P. jiroveci</i> , <i>Fusariums</i> species; Zygomycosis; other molds, such as <i>Pseudallescheria</i> species

Acquired or Iatrogenic conditions

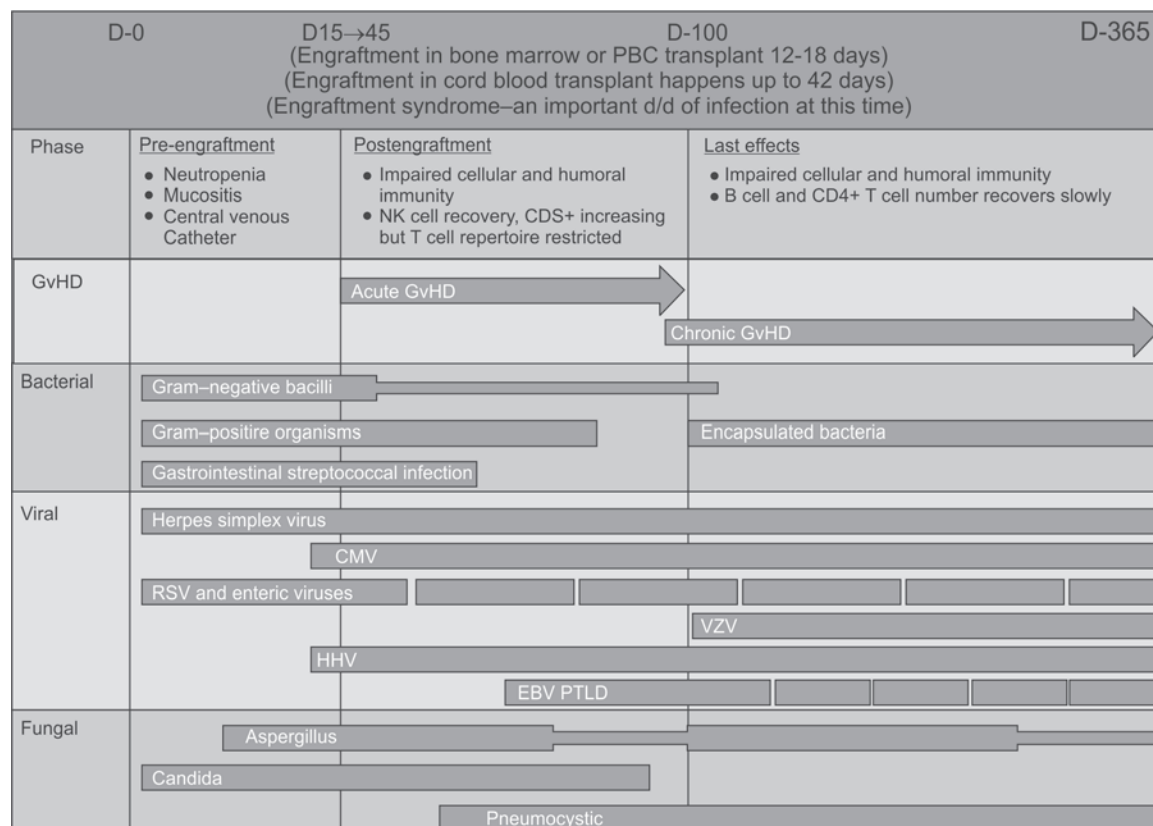

Solid organ transplant	Reactivation of old infections (tuberculosis), but usually the infections are transplant specific	Viral Infections nonspecific to organ transplant- Respiratory syncytial virus, influenza, CMV, VZV, HSV, EBV, BK virus, JC virus Heart or Heart Lung Transplant: <i>P. jiroveci</i> and <i>Toxoplasma</i> species Renal transplant: Adenovirus and BK virus and early post-transplant infections particularly with aspergillosis, cryptococcosis and zygomycosis
------------------------	---	---

with individual bacterial infections and a broad guideline for the bacterial management would be discussed under the febrile neutropenia and the commoner viral and fungal infections would be covered under separate headings.

The patients of hematopoietic stem cell transplant (HSCT) deserve a special mention. It's thought to be secondary to the immune reconstitution following HSCT and the type and the timing of infection depend on the recovery of various facets of immune system. The details of the immune recovery are given in the next chapter, i.e. "Vaccination of the immunocompromised host". Whether, It's secondary to allogenic or autologous (high dose chemotherapy followed by patient's own stem cell rescue, collected and cryopreserved at an earlier time) HSCT the

chances of infection are very high. The period of immunodeficient time is prolonged in the patients of allogenic HSCT in comparison to autologous HSCT. A brief timeline for the type of infections is given in the Figure 1.¹⁴

One of the big group among the immunocompromised hosts is constituted by the kids postchemotherapy and then presenting as febrile neutropenia. The most recent guideline of the Infectious Diseases Society of America (IDSA),¹⁵ states that in patients with febrile neutropenia the gram-positive bacteria are responsible for ~ 60 percent of microbiologically confirmed cases and the important ones are coagulase-negative staphylococci, vancomycin resistant enterococci, *S. aureus*, *pneumococcus* and *streptococcus viridans*. The recent years have shown an

D: Day; GvHD: graft versus host disease; CMV: cytomegalovirus; RSV: respiratory syncytial virus; VZV: varicella zoster virus; HHV: human herpes virus; EBV PTLD: Epstein Barr virus post-transplant lymphoproliferative disease; Bars: thicker the bar commoner the infection, thinner the bar vice versa.

Fig. 1: Time line for infection in patients with HSCT¹⁴

increase in the incidence of gram-positive bacteria may be secondary to the invasive procedures in these kids. Gram-negative bacteria are the second common group and the significant ones are *P. aeruginosa* and enterobacteria, especially *Klebsiella* spp. and *E. coli*, many of which, depending on local epidemiology, are extended-spectrum beta-lactamase (ESBL) producers.¹⁵ The likelihood of an infection varies from the unit to unit and hospital to hospital based on their practices. The guidelines given here are to be seen as a suggestion in their perspectives. Other etiologic agents, such as fungi and mycobacteria, may affect, with lower frequency, febrile neutropenic patients and are normally related to more severe and prolonged episodes of neutropenia (neutrophil $<500/\mu\text{L}$ and neutropenia for more than 10 days), to previous and prolonged wide spectrum antimicrobial use or antifungal prophylaxis and bone marrow or hematopoietic stem cell transplantation.¹⁶

DIAGNOSIS OF INFECTION

The diagnosis of sepsis in immunocompromised host is the pivotal step in the management and the clinical diagnosis should always be supported with lab diagnostics. The clinical diagnosis of infections in immunocompromised individuals is always a challenge as the clinical picture is always subtle secondary to the suboptimal inflammatory response in these kids. Having said that, usually it might not be possible to establish an infectious agent in the laboratory so early clinical diagnosis or suspicion holds the key for early interventions and thereby decreasing the mortality and morbidity. Definitive diagnosis might not always be possible and delaying the treatment might lead to devastating outcome in these patients so clinical suspicion of an infection is a good enough reason to start the targeted treatment (antibiotics, antiviral or antifungals) in these kids pending the lab results and then treatment to be titrated as per the course of the illness.

Since these patients are a heterogeneous population, but still if the patient is with a known diagnosis and is on immunosuppressive agents, making a clinical diagnosis is not difficult. If it's a new patient there are few clinical parameters which connote a possible immunocompromised condition and these are >10 episodes of acute otitis media, >2 episodes of pneumonia, >2 life-threatening infections per year, unusual pathogens causing infection, poor response of the normal pathogens to the standard of therapy, recurrent episodes of autoimmune phenomena, infections causing worsening of the chronic illnesses, poor immune response to vaccines, family history of immunodeficiency or similar infections, failure to thrive and developmental delays, chronic eczema, diarrhea and thrush.¹⁷

To establish a diagnosis, the laboratories tests to be done initially and then as add-on according to the suspected clinical condition are listed in Table 4.¹²

MANAGEMENT

Given the vast scope of the subject it might not be possible to include all the infections in the given chapter. We will cover the management of the bacterial illnesses under febrile neutropenia, and then the common and important viral and fungal infections would be discussed in brief.

Febrile Neutropenia

Any patient with neutropenia and fever is grouped in febrile neutropenia but majority of the patients fall into either of the two categories. First category involves patients which are neutropenic secondary to the bone marrow failure syndromes (single or multilineage), cyclical neutropenia, or benign neutropenia of the infancy (autoimmune neutropenia). Second group contains the patients who are neutropenic secondary to the chemotherapy given. Febrile neutropenia usually is used for neutropenia secondary to the chemotherapy.

Infectious Diseases Society of America (IDSA) guidelines define neutropenia as a neutrophil count of 500 cells/mm^3 or less or a count of $<1,000 \text{ cells/mm}^3$ with a predicted decrease to $<500 \text{ cells/mm}^3$ and fever in a neutropenic patient is defined as a single measurement of oral temperature of more than 38.3°C or a temperature of $>38.0^\circ\text{C}$ for $>1 \text{ h}$.¹⁸ The combination of the above two is known as febrile neutropenia. The diagnosis of febrile neutropenia warrants an immediate antibiotic support based on the risk grouping. Infectious disease society of America in their consensus guideline gave the criteria to divide the patients in to either low risk group or the high risk group for the initial decision of antibiotic selection and management strategies.¹⁸ Table 5 summarizes the commonly used criteria to group patients in the risk categories.^{18,19}

Once the patient is assigned a risk group the management starts. There is no gold standard hard and fast rule for antibiotic selection and the Figure 5 gives only the suggestions. A detailed antibiotic policy as per the prevalent common infections in the hospital and their culture sensitivity reports is a sound antibiotic policy for any individual unit and should be followed up closely.

Infectious Disease Society of America (IDSA) 2010, recommendations for the evaluation and treatment of patients with fever and neutropenia.¹⁵ A summary (strength of recommendation is given in parenthesis)

Role of risk assessment and what distinguishes high-risk and low-risk patients:

Assessment should be done at presentation of fever (A-II), this may determine the type of empirical antibiotic therapy (oral vs intravenous), if an admission needed (inpatient vs outpatient), and the duration of antibiotic therapy (A-II). Most high-risk patients should be initially admitted to the hospital for empirical therapy (A-II). Low-risk patients are candidates for oral empirical therapy (A-II).

Table 4: Lab work to be done as per the suspected condition¹²

<i>Blood test</i>		<i>Cultures</i>	<i>Radiological</i>	<i>Microbiological</i>
Initial lab work, non-specific to condition	CBC with differential with morphology ESR and C-reactive protein Renal and liver function tests and coagulation studies if indicated Blood urea, Creatinine, electrolytes, liver transaminases, total and direct bilirubin and amylase	Cultures: Every immunocompromised patient if febrile need a vigorous search for infection through various cultures. Depending on the various factors like, central venous line <i>in situ</i> , previous known infection, and productive sputum or discharges a blood culture and a culture of the other body fluids is taken up. If CVL <i>in situ</i> , a pair of blood culture (one from CVL and second from peripheral phlebotomy) is taken ideally. We need to repeat the blood cultures daily in order to increase the yield.	Depending on the organ system of presentation, may order for chest X-ray or ultrasound of the chest or abdomen or CT scan of the head (with or without contrast, as advised by the initial condition)	Rapid antigen testing as indicated and includes, group A streptococci, <i>C. difficile</i> , <i>Cryptococcus</i> species, RSV, influenza virus, adenovirus and parainfluenza
<i>Additional test to be done as per the suspected condition</i>				
B cells evaluation	Ig levels IgG subclass levels Isohemagglutinins Lymphocyte subpopulations (CD19 or CD20)	Daily blood cultures if patient stays febrile or suspected of running infection and add other cultures as and when required	CXR/CT chest to look for a thymus and/or lymphoid tissue	Antibody production after vaccination (e.g. diphtheria, meningococcal, pneumococcal and Tetanus)
T cells evaluation	Lymphocyte subpopulations Assessment of delayed-type hypersensitivity reactions	Daily blood cultures if patient stays febrile or suspected of running infection and add other cultures as and when required	CXR/CT chest to look for a thymus and/or lymphoid tissue	Mitogen-stimulation assays
Phagocytic evaluation	Absolute neutrophil count Numbers of CD11(a, b and c subset) and CD18 β -receptor	Daily blood cultures if patient stays febrile or suspected of running infection and add other cultures as and when required	CXR/CT chest to look for a thymus and/or lymphoid tissue	Chronic granulomatous disease assay (formerly nitroblue tetrazolium test)
Complement evaluation	Total hemolytic complement MBL levels (mannose-binding lectin) Specific complement components, e.g. C3, C4, etc.	Daily blood cultures if patient stays febrile or suspected of running infection and add other cultures as and when required	CXR/CT chest to look for a thymus and/or lymphoid tissue	CH50 evaluation

Table 5: Risk groups assignments in patients with febrile neutropenia

	<i>Low risk for severe infection</i>	<i>High risk for severe infection</i>
Factors	ANC $\geq 100/\text{mm}^3$ AMC $\geq 100/\text{mm}^3$ Normal chest X-ray Nearly normal hepatic and renal function tests Duration of neutropenia of < 7 days Resolution of neutropenia expected in < 10 days No intravenous catheter–site infection Early evidence of bone marrow recovery Malignancy in remission Peak temperature of $< 39.0^\circ\text{C}$ No neurological or mental changes Nontoxic appearance and no abdominal pain No comorbid complications ^a	ANC $< 100/\text{mm}^3$ Toxic appearance Comorbid complications ^a Abnormal chest X-ray Abnormal hepatic and renal function tests Resolution of neutropenia expected in > 10 days Intravenous catheter <i>in situ</i> Malignancy not in remission Signs of CNS involvement

ANC: Absolute neutrophil count; AMC: absolute monocyte count; a: shock, hypoxia, pneumonia or other deep-organ infection, vomiting, or diarrhea.^{18,19}

Multinational Association for Supportive Care in Cancer (MASCC) scoring system (B-I) may be used to put the patient in Risk groups.

- High-risk patients have a MASCC score <21 (B-I) and Low-risk patients have a MASCC score >21 (B-I).

What specific tests and cultures should be performed during the initial assessment?

Complete blood cell (CBC) count with differential leukocyte counts; serum creatinine, blood urea nitrogen; electrolytes, hepatic transaminases and total bilirubin and a chest X-ray with respiratory signs and symptoms (A-III). Two sets of blood cultures are recommended (AIII). Blood culture volumes should be limited to 0.1 percent of total blood volume (CIII):

- If CVC (central venous catheter) present—Collect simultaneously from each lumen of CVC, and from a peripheral vein site.
- If no CVC—Two blood culture sets from separate venipunctures should be sent.

Culture specimens from other sites of suspected infection should be obtained as clinically indicated (A-III).

What empiric antibiotic therapy is appropriate?

High-risk patients require hospitalization for IV empirical antibiotic therapy; monotherapy with an antipseudomonal β -lactam agent, such as cefepime, a carbapenem (meropenem or imipenem-cilastatin), or piperacillin-tazobactam, is recommended (A-I). Other antimicrobials (aminoglycosides, fluoroquinolones, and/or Vancomycin) may be added to the initial regimen for management of complications (e.g. hypotension and pneumonia) or if antimicrobial resistance is suspected or proven (B-III). Vancomycin or other agents active against gram-positive cocci are not recommended as a standard part of the initial antibiotic regimen for fever and neutropenia (A-I) but may be considered for suspected catheter-related infection, skin or soft-tissue infection, pneumonia, or hemodynamic instability. Modifications to initial empirical therapy may be considered for patients at risk for infection with the following antibiotic-resistant organisms, (B-III):

- MRSA (methicillin-resistant *Staphylococcus aureus*): Consider early addition of Vancomycin, Linezolid, or Daptomycin (B-III).
- VRE (vancomycin-resistant *Enterococcus*): Consider early addition of linezolid or daptomycin (B-III).
- ESBLs (Extended-spectrum β -lactamase): Consider early use of a carbapenem (B-III).
- KPCs (*Klebsiella pneumoniae* carbapenemase): Consider early use of polymyxin-colistin or tigecycline (C-III).

Penicillin-allergic patients—usually tolerate cephalosporins, but those with severe reaction should avoid β -lactams and carbapenems and be given combinations

such as ciprofloxacin plus clindamycin or aztreonam plus vancomycin (A-II).

Low-risk patients should receive initial oral or IV empirical antibiotic doses in a clinic or hospital setting; and then they may be transitioned to outpatient oral or IV treatment as per their progress (A-I).

Ciprofloxacin plus amoxicillin-clavulanate in combination is recommended for oral empirical treatment (A-I). Other option includes levofloxacin or ciprofloxacin monotherapy or ciprofloxacin plus clindamycin (B-III). Patients receiving fluoroquinolone prophylaxis should not receive therapy with another or the same fluoroquinolone (A-III). (Issue - use of quinolones in the early childhood is of concern. Few pediatric oncology centers uses oral Cephalosporine (Cefpodoxime) also)

How to make antimicrobials modifications?

Modifications should be made based on clinical and microbiologic data (A-II). Persistent fever without an obvious cause and otherwise stable, rarely need a change to the initial antibiotic regimen (A-I).

Documented infections should be treated with antibiotics as per the culture and sensitivity report (A-I). If vancomycin was started initially, and there is no evidence for gram-positive infection, it may be stopped after 2 days (A-II). Patients who are hemodynamically unstable even after the standard agents for neutropenic fever should have a broadened antibiotic coverage for resistant gram-negative, gram-positive, and anaerobic bacteria and fungi (A-III).

Low-risk patients who are on IV or oral antibiotics, clinically stable but in hospital should be offered a simplified antibiotic coverage (A-I) and a transition to outpatient care with daily follow-up. If fever persists or recurs within 48 h in outpatients, hospital readmission is recommended, with management as for high-risk patients (A-III).

High-risk patients should be offered an empirical antifungal coverage that have persistent fever after 4 to 7 days of a broad-spectrum antibacterial regimen and no identified fever source (A-II).

Duration of antibiotic therapy?

In *documented infections*, the duration of therapy depends on the organism and site; appropriate antibiotics to be given at least during the neutropenia (until ANC is >500 cells/mm³) or longer if clinically necessary (B-III).

In *nondocumented fevers*, the initial antibiotics to be continued until there are signs of marrow recovery. Once ANC exceeds 5000 cells/mm³, antibiotics can be stopped (B-II).

If patient is afebrile with resolved clinical signs of nondocumented infections and initial course of antibiotics completed but are still neutropenic, should be given appropriate oral antibiotic prophylaxis until marrow recovery (C-III).

Antibiotic prophylaxis?

Appropriate prophylaxis (unit policy based on microbiological data) should be given for high-risk patients (BI). Addition of a gram-positive active agent is generally not recommended (A-I). Antibacterial prophylaxis is not routinely recommended for low-risk patients (A-III).

Empirical or pre-emptive antifungal therapy?

In *high risk* patients where fever is persisting or recurring after 4 to 7 days of antibiotics, should be considered for empirical or pre-emptive (evaluated with CT chest and sinuses with ultrasound abdomen and reports are normal) antifungal therapy (A-I). There is no consensus for selecting a specific empirical antifungal agent for a patient who is already receiving antimold prophylaxis, but switching to a different class of antimold antifungal with intravenous route should be considered (B-III).

In *low risk patients*, routine use of empirical antifungal therapy is not recommended (A-III).

Antifungal prophylaxis?

In *high risk* patients prophylaxis against *Candida* infection is recommended (A-I). Fluconazole, itraconazole, voriconazole, posaconazole, micafungin, and caspofungin are all acceptable agents depending on the units policy. Patients who are undergoing intensive chemotherapy for acute myeloid leukemia (AML) or myelodysplastic syndrome (MDS) should be offered anti-aspergillus prophylaxis (B-I).

In patient with autologous or allogenic hematopoietic stem cell transplant, prophylaxis against *Aspergillus* infection before engraftment has not been shown to be efficacious. However, in patients with prior invasive aspergillosis, a mold-active agent is recommended (A-III).

In *low risk* patients antifungal prophylaxis is not recommended (A-III).

Antiviral prophylaxis?

Patients undergoing allogeneic HSCT or leukemia induction therapy and are seropositive should receive a herpes simplex virus (HSV) antiviral prophylaxis with Acyclovir (A-I). Treatment for HSV or varicella-zoster virus (VZV) infection is only indicated if there is clinical or laboratory evidence of active viral disease (C-III).

Influenza virus infection should be treated with neuraminidase inhibitors if the infecting strain is susceptible (A-II). In a situation like influenza exposure or outbreak, if a neutropenic patient presents with influenza-like illness, should receive treatment empirically (C-III). Routine treatment of RSV infection in neutropenic patients with upper respiratory disease should not be given (B-III).

Hematopoietic growth factors (G-CSF or GM-CSF)?

Hematopoietic growth factors should be considered for patients in whom the anticipated risk of fever and

neutropenia is >20 percent (A-II) but are not generally recommended for treatment of established fever and neutropenia (B-II).

Catheter-related infections?

Differential time to positivity (DTP) >120 min (CVC related samples are positive earlier than then the taken from peripheral vein) of qualitative blood cultures performed on specimens simultaneously drawn from the central venous catheter (CVC) and a peripheral vein suggests a central line-associated blood stream infection (CLABSI) (A-II).

- CLABSI caused by *S. aureus*, *P. aeruginosa*, fungi or mycobacteria, catheter removal is recommended in addition to systemic antimicrobial therapy for at least 14 days (A-II). Catheter removal is also recommended for tunnel infection or port pocket site infection, septic thrombosis, endocarditis, sepsis with hemodynamic instability, or blood stream infection that persists despite >72 h of therapy with appropriate antibiotics (A-II).
- CLABSI caused by coagulase-negative staphylococci, the catheter may be retained using systemic therapy with or without antibiotic lock therapy (B-III).
- Prolonged treatment (4-6 weeks) is recommended for complicated CLABSI, defined as the presence of deep tissue infection, endocarditis, septic thrombosis (A-II) or persistent bacteremia or fungemia occurring 72 h after catheter removal in a patient who has received appropriate antimicrobials (A-II for *S. aureus*, C-III for other pathogens).

VIRAL INFECTIONS

Viral infections are a common cause of the serious disease in immunocompromised hosts. In the last twenty years, several potent new antiviral agents have become available for the effective management of infections like herpes simplex virus (HSV), varicella-zoster virus (VZV), and cytomegalovirus (CMV).²⁰⁻²³ In the last decade, major advances in rapid diagnostic techniques for viral infections have further helped to markedly improve the efficacy of antiviral treatment. Last few years have seen the refined antigen detection assays, polymerase chain reaction (PCR) and Shell-vial cultures helping the clinician to detect viral infections at an early stage and making timely therapeutic decisions. It will be beyond the scope of the chapter to include all the viral infection here but the common infections will be discussed here in brief (Table 6).

Influenza

Influenza (flu) virus is a RNA virus from the family orthomyxoviridae and affects birds and mammals. Influenza viruses make up three of the five genera of the family orthomyxoviridae²⁴ influenza virus A, B and C. For

Table 6: Management strategies for the common viral infections in the settings of immunocompromised hosts

<i>Virus</i>	<i>First line treatment</i>	<i>Second line treatment</i>	<i>Diagnosis</i>	<i>Comment</i>
HSV	Acyclovir (IV, oral), high dose IV—250 mg/m ² Q8H x 10 D Use 500 mg/m ² for visceral Oral: <2 yrs—200 mg QID 2-6 yrs—400 mg QID >6 yrs—800 mg QID Valacyclovir (oral), high dose PO—500 mg BID x 10 D	Foscarnet (IV)* IV—60 mg/kg Q8H Cidofovir (IV) IV—1 mg/kg alternate days	Serology, viral cultures, viral antigens and viral DNA PCR and Tzanck smear from the lesions	Give preferably in central line if using IV and monitor serum creatinine
VZV	Acyclovir (IV, oral), high dose IV—500 mg/m ² Q8H x 14 D Oral- <2 yrs—200 mg QID 2-6 yrs—400 mg QID >6 yrs—800 mg QID VZV immune globulin in <96 hrs <5 years—250 mg IV stat 5-10 years—500 mg IV stat and >10 years—750 mg IV stat	Famciclovir* PO—500 mg three times a day	Viral cultures, viral antigens and viral DNA PCR	Give preferably in central line if using IV and monitor serum creatinine
ADV	Cidofovir (IV) IV—5 mg/kg/week x 3 wks as induction and then 5 mg/kg/alternate wks x 3 wks (continue as per unit policy)	Vidarabine (IV)* IV—10 mg/kg/day x 5-7 Days in one course (number of courses as per unit policy)	Viral cultures, viral antigens by immunofluorescence in urine, stool and blood and viral DNA PCR	Coadministered with Probenecid and monitor serum creatinine
CMV	Gancyclovir (IV) Induction: IV—5 mg/kg Q12H Consolidation: IV—6 mg/kg once daily x 5 D/wk Cytogam (CMV immunoglobulin) IV—50 mg/kg once a wk	Foscarnet (IV)* Induction: IV—60 mg/kg Q12H Consolidation: IV—90 mg/kg once daily x 5D/wk	Serology, viral cultures, viral antigens and viral DNA PCR	May cause neutropenia (consider G-CSF) Neurotoxicity in patients with renal impairment
RSV	Ribavirin (inhalation, IV, oral) Aerosolized—6 g over 18 h/day at 20 mg/ml, for 7 days via a respiratory small particle aerosol generator 'SPAG unit') and + IVIg (500 mg/kg/dose alternate days for four doses)	Palivizumab# (Humanized RSV monoclonal antibody) IV—15 mg/kg single dose (courses number as per unit policy)	Immunofluorescence and enzyme immunoassay for RSV antigen in nasopharyngeal washings or bronchoalveolar lavage	Therapeutic benefit in RSV infection unclear outside allogeneic stem cell
HBV	Pegylated Interferon α-2a (180 µg once weekly) + Lamivudin (Oral) PO—3 mg/kg/day x 48-56 wks		Serology and HBV DNA PCR	Prevention of acute liver failure in patients with active HBV replication
Influenza	Oseltamivir (oral) x 10 D <15 kg—30 mg BD 15-25 kg—45 mg BD 25-40 kg—60 mg BD >40 kg—75 mg BD (150 mg BD x 10 days in severe infection)	Zanamivir (inhalation) x 5 mg inhalation once daily x 10 D	Viral culture, serology, rapid antigen testing, immunofluorescence assays and viral PCR	Administer as early as possible (<48 h) after diagnosis. Infants safety not established and use not recommended \$—Administer as early as possible (<48 h) after diagnosis

EB virus	Donor leukocyte infusion rituximab (Anti-CD20) (IV)	EBV specific cytotoxic T lymphocytes Chemotherapy	EBV PCR for viral load Post-transplant lymphoproliferative disease- Tissue biopsy for evidence of Lymphoproliferation + Ebstein barr virus load	Data from EBV associated lymphoproliferative disease after transplantation

HSV: herpes simplex virus; VZV: varicella zoster virus; ADV: adenovirus; CMV: cytomegalovirus; RSV: respiratory syncytial virus; HBV: hepatitis B virus; EBV: Epstein-Barr virus; #: no randomized study, small case series with conflicting results; *: evidence from case reports only

Influenza-A virus, wild aquatic birds are the natural hosts. Occasionally, viruses are transmitted to other species and sometimes cause devastating outbreaks in domestic poultry or give rise to human influenza pandemics.²⁵ The type-A viruses are the most virulent human pathogens among the three influenza types and cause the most severe disease and latest pandemic of swine flu (2009) is one of the examples. The virulence increases exponentially in immunosuppressed patients. Influenza-B almost always infects humans²⁶ and is less common than influenza A. Influenza B viruses are less genetically diverse, with only one serotype²⁶ and because of this less antigenic diversity immunity to influenza B is usually acquired at an early age. Influenza-C is less common than the other types and usually causes mild disease in children.

Flu in humans present as sore throat, cough, fever, chills, malaise, myalgia, headache, fatigue and nausea and vomiting particularly in the children.²⁷ Although it is often confused with other influenza-like illnesses, especially the common cold but influenza is a more severe disease. Flu can occasionally cause either direct viral pneumonia or secondary bacterial pneumonia.²⁸ Influenza is transmitted through the droplets containing the viruses. Influenza can also be transmitted by direct contact with bird droppings or nasal secretions, or through contact with contaminated surfaces, though the most important means of transmission is not clear.²⁹ Influenza viruses can be inactivated by sunlight, disinfectants and detergents.^{30,31} As the virus can be inactivated by soap, frequent hand washing reduces the risk of infection significantly.³²

Influenza A and B viruses are responsible for important morbidity and mortality in profoundly immunocompromised patients.^{33,34} In a study in immunosuppressed adults, out of all influenza infections pneumonia developed in approximately two-thirds of these patients with a case-fatality rate of up to 50 percent.³³ The severity of influenza in immunosuppressed patients appears to be related to the degree and duration of immunosuppression. Amantadine and Rimantadine are the effective treatment options for influenza-A infection. However, the benefit of the prophylactic or therapeutic use of these compounds in immunosuppressed individual is uncertain.

The neuraminidase inhibitors Zanamivir and Oseltamivir are active against both influenza A and B viruses. Several placebo-controlled trials have documented the efficacy and safety of neuraminidase inhibitors in the treatment of influenza in immunocompetent adults.³⁵ Studies are needed to assess the role of these antiviral agents in immunosuppressed patients. To reduce the risk of nosocomial transmission of influenza viruses, infection control measures and immunization with influenza virus vaccine of patients and hospital personnel are recommended.^{36,37}

Cytomegalovirus

Cytomegalovirus (CMV) has its origin from the Greek words, Cyto means- “cell”, and Megalo means, “large”. It is typically abbreviated as CMV. The species that infects humans is commonly known as human CMV (HCMV) or human herpesvirus-5 (HHV-5), and is the most studied of all cytomegaloviruses.³⁸ Human cytomegalovirus is a species of virus that belongs to the viral family known as Herpesviridae or herpesviruses. It is typically abbreviated as HCMV and is alternatively known as human herpesvirus-5 (HHV-5).³⁸ Within Herpesviridae, HCMV belongs to the Betaherpesvirinae subfamily, which also includes cytomegaloviruses from other mammals.³⁹ Although they may be found anywhere in the body, HCMV infections are frequently associated with the salivary glands.³⁹ In health individuals, HCMV infection is not clinically significant, but can be life-threatening for the immunocompromised persons and newborn infants.³⁸ After infection, HCMV has an ability to remain latent within the body over long periods and gets activated whenever body gets severely immunosuppressed.

CMV infection, is usually defined as the isolation of CMV in tissue culture or the identification of markers for CMV in tissue specimens or blood by histologic and histochemical means, or by specific antigen staining, by direct CMV DNA/RNA or CMV antigen detection, or by a four-fold or higher rise in CMV antibody titer.⁴⁰

CMV-associated interstitial pneumonia is defined as a progressive interstitial pulmonary process, as evidenced by chest X-ray findings and increased hypoxia, with evidence

of CMV infection in the lung and without evidence for other causes of pneumonitis. CMV enteritis is defined as an enteropathic syndrome with pain, nausea and vomiting, or diarrhea and evidence of CMV infection at the site of an inflammatory or ulcerative mucosal lesion. In general, other CMV-associated organ-related syndromes, such as hepatitis and encephalitis, are defined as syndromes with specific organ dysfunction and the concomitant presence of active CMV infection. With the exception of CMV retinitis, the diagnosis of CMV disease cannot be made without histologic evidence of CMV infection in the involved organ.

Immunosuppressed patients are at high risk for serious CMV disease following primary infection, reinfection, or reactivation of virus. Patients of allogeneic hematopoietic stem cell transplant (HSCT) are particularly at risk for CMV disease and the strongest predictor of CMV infection after allogeneic HSCT is the pretransplant CMV seropositivity of the patient. Failure to reconstitute a CMV-specific CD8+ cytotoxic T-cell response after HSCT contributes to the risk for CMV infection.^{41,42} CMV viremia is a major predisposing factor for CMV pneumonia and gastrointestinal CMV disease. In patients with acute leukemia, CMV pneumonia was reported to occur in 2.9 percent of patients with a case-fatality rate of 57 percent.⁴³ Even with the best possible therapy, CMV pneumonia after HSCT is associated with a mortality rate of 45 to 78 percent.^{44,45} Thus, in patients of HSCT and severe immunocompromised hosts, primary emphasis is given on the prevention of CMV disease.

It's well established now that even high-dose intravenous acyclovir as a prophylactic agent given only partial protection from CMV disease after allogeneic HSCT, and is absolutely ineffective in autograft recipients.⁴⁶ Prophylaxis with IV ganciclovir results in less frequent CMV disease but overall no improved survival⁴⁷ but on the other hand, if pre-emptive ganciclovir therapy initiated promptly upon recognition of CMV infection, is associated with both decreased incidence of CMV disease and better survival also.⁴⁸ The pre-emptive IV foscarnet appears as efficacious as ganciclovir and is associated with less hematotoxicity.⁴⁹ Results of a retrospective study, showed that IV cidofovir may be used in the treatment of CMV infection in HSCT recipients.⁴⁵

Valganciclovir is an oral prodrug of ganciclovir with a ten-fold greater bioavailability compared to oral ganciclovir.⁵⁰ Systemic ganciclovir exposure achieved with valganciclovir is comparable to that of intravenous ganciclovir.⁵⁰ The pharmacokinetics and safety of oral valganciclovir after allogeneic SCT are currently being investigated.

EBSTEIN-BARR VIRUS

Epstein-Barr virus (EBV), also known as human herpesvirus 4 (HHV-4), is a virus from the herpes family. It is best

known as the cause of infectious mononucleosis in immunocompetent individuals. It has been also associated with particular forms of cancer, particularly Hodgkin's lymphoma, Burkitt's lymphoma, nasopharyngeal carcinoma, and central nervous system lymphomas in patients with human immunodeficiency virus.⁵¹

Primary infection in normal hosts results in infectious mononucleosis (transient lymphoproliferative disorder), that is restricted by cytotoxic and suppressive lymphocytes. However, in the immunocompromised hosts, EBV-induced lymphoproliferation behave in a biologically malignant fashion and ranges from fulminant mononucleosis and invasive polyclonal B cell hyperplasia to monoclonal B cell malignancies known as post-transplant lymphoproliferative disease (PTLD).⁵²

Severe infections by Epstein-Barr virus (EBV) are relatively uncommon following HSCT, but if they happen, the most serious one is EBV related PTLD. PTLD is the result of the uncontrolled proliferation of donor derived EBV+B cells due to the lack of T cell immunity. The most significant risk factors for developing PTLD include the use of unrelated donor grafts (hematopoietic or solid organ grafts), T cell depletion of hematopoietic donor grafts, the use of OKT-3 for prophylaxis against rejection, or the treatment of acute graft versus host disease (GVHD) leading to more immunosuppression, and having received antithymocyte globulin.^{53,54} This suggests that selective T-cell depletion results in depletion of immunoregulatory T cells while leaving behind EBV+B cells that are susceptible to uncontrolled proliferation. PTLD occurs in <2 percent of allogeneic-HSCT⁵³ and typically occurs during the first six months after transplant. PTLD occurring after the first year post HSCT have been reported and occur mainly in patients with chronic GVHD where more immunosuppression is used.⁵³

Clinical manifestations of PTLD include fever, anorexia, lymphadenopathy, lethargy or confusion, hepatitis, or hepatosplenomegaly.⁵⁵ The diagnosis of PTLD is made by biopsy of affected organs. EBV serology is not helpful in establishing a diagnosis of PTLD, but monitoring changes in viral load may be useful. EBV DNA can be detected in >60 percent of allogeneic BMT recipients but isolated increase in the EBV DNA doesn't mean PTLD.⁵⁶ The difference in the load and the clinical picture holds the key to diagnosis. Patients with PTLD have a significantly higher viral load compared to patients without PTLD.⁵⁶ Even in patients with sustained increases in EBV viral load, only approximately 50 percent will develop PTLD.⁵⁷ In addition, the predictive value of threshold viral load may vary from center to center,^{56,57} and the patients' individual risk for PTLD must be taken into account when acting on PCR results. The interval between first demonstrating a rise in viral load and clinical signs of PTLD is often short.

Regional and node-based polyclonal proliferations may respond to prompt reduction of immunosuppressive

therapy and efforts to interrupt the replicative cycle with antiviral agents. Systemic cytotoxic therapy often leads to further immunosuppression and should be reserved for patients with progressive disease, advanced visceral involvement, and monoclonal lymphoid malignancies.

Successful treatments for PTLD have included donor leukocyte infusions,⁵⁸ EBV specific cytotoxic T lymphocytes,⁵⁹ chemotherapy,⁶⁰ and anti-CD20 monoclonal antibodies.^{56,61,62} Anti-CD20 antibodies (rituximab) are commercially available, thus making them attractive choices for therapy. Pre-emptive treatment with rituximab based on rising EBV DNA titers has prevented the development of PTLD in one series.⁶¹ Both pre-emptive rituximab treatment based on viral load and treatment at the first clinical signs of PTLD can be effective therapy, although initiating treatment only when patients demonstrate a high viral load may result in the unnecessary treatment of some patients.

HERPES SIMPLEX VIRUS

Herpes simplex virus (HSV) 1 and 2 (HSV-1 and HSV-2), also known as human herpes virus 1 and 2 (HHV-1 and -2), are two members of the herpes virus family, Herpesviridae, that infect humans.⁶³ Both HSV-1 (which produces most cold sores) and HSV-2 (which produces most genital herpes) are ubiquitous and contagious. They can be spread when an infected person is producing and shedding the virus. HSV types 1 and 2 are a common cause of mucocutaneous lesions in immunosuppressed patients.⁶⁴

Symptoms of herpes simplex virus infection include watery blisters in the skin or mucous membranes of the mouth, lips or genitals.⁶³ Lesions heal with a scab characteristic of herpetic disease. Sometimes, the viruses cause very mild or atypical symptoms during outbreaks. However, as neurotropic and neuroinvasive viruses, HSV-1 and -2 persist in the body by becoming latent and hiding from the immune system in the cell bodies of nerves. After the initial or primary infection, some infected people experience sporadic episodes of viral reactivation or outbreaks. In an outbreak, the virus in a nerve cell becomes active and is transported via the nerve's axon to the skin, where virus replication and shedding occur and cause new sores.⁶⁵

HSV encephalitis is a rare complication even in immunosuppressed individuals. It occurs in the general population with a frequency of 1 in 250,000 to 500,000 persons per year, and does not appear to be more common even in HSCT patients which are severely immunocompromised.⁶⁶ In the "normal" host, the clinical presentation consists of acute onset of fevers and focal, primarily temporal lobe, neurologic signs and symptoms. However, in the immunocompromised host, the presentation is atypical, with a subacute but progressively deteriorating course.

Diagnosis of HSV infection relies upon both clinical and laboratory criteria. Sometimes, clinically it might

be difficult differentiating between HSV and VZV. In the past, rapid diagnosis of cutaneous lesions was made with adequate scrapings of fresh, early lesions examined microscopically after Giemsa (Tzanck preparation), Wright or Papanicolaou staining. The demonstration of intranuclear inclusions and/or giant cells confirmed a diagnosis of herpesvirus infection. However, these staining techniques do not differentiate between HSV and VZV, and therefore the preferred test is for HSV (and VZV) antigens or DNA. These scrapings can be submitted for antigen detection by direct fluorescent antibody, peroxidase or enzyme-linked methods. These are highly specific and sensitive tests if the specimens are obtained early in newly erupted lesions. Polymerase chain reaction (PCR) can be used to detect HSV DNA in swabs or scrapings from mucocutaneous lesions, is more sensitive than culture, and many centers now use it as the standard of practice.⁶⁷ The gold standard of diagnosis of HSV infection is virus isolation. The positive culture will also provide the laboratory with an isolate that can subsequently be tested for antiviral resistance. Culture for HSV is particularly important when acyclovir resistance is suspected. A cytopathic effect may develop within 24 to 48 hours, but definitive identification may take from 48 to 96 hours. A tissue biopsy is usually required to make a diagnosis of visceral HSV infection. The diagnosis for HSV encephalitis made through isolation of the virus from brain tissue. However, the current method of choice is the much less invasive test of HSV DNA determination by PCR of cerebrospinal fluid.⁶⁸

Herpes simplex virus (HSV) infection results in most cases from reactivation of latent virus, thus antiviral drug prophylaxis is primarily given to HSV seropositive patients. Antiviral drug treatment including, acyclovir, valaciclovir and famciclovir is aimed both at shortening the duration of HSV disease and at preventing the dissemination of HSV to visceral sites which can lead to life-threatening disease.^{64,69,70} Prophylactic intravenous or oral acyclovir has become a standard of care for HSV seropositive cancer patients during periods of profound immunosuppression.⁶⁴ Valaciclovir and famciclovir have an oral bioavailability 3-5 times superior to that of oral acyclovir.

In HSCT patients, it has been proved that the risk of HSV reactivation is proportional to the pretransplant HSV immunoglobulin G titer.⁷¹ The allogeneic HSCT recipients who develop acute graft-versus-host disease are on prolonged immunosuppression and usually require a prolonged HSV prophylaxis.

Although not systematically studied, Oral valaciclovir is commonly used in the prevention of HSV reactivation after HSCT. Intravenous acyclovir remains the therapy of choice for severe mucocutaneous or visceral HSV disease in immunocompromised hosts.^{64,69-70} Oral acyclovir, valaciclovir, or famciclovir may be considered as alternative therapies for less serious manifestations of HSV disease.⁷⁰

Varicella-Zoster Virus

Varicella zoster virus (VZV) is one of pathogenic herpes viruses known to infect humans. VZV is also known as chickenpox virus, varicella virus, zoster virus, and human herpes virus type 3 (HHV-3). Primary VZV infection results in chickenpox (varicella), which may rarely result in complications including encephalitis or pneumonia. Even when clinical symptoms of chickenpox have resolved, VZV remains dormant in the nervous system of the infected person (virus latency), in the trigeminal and dorsal root ganglia.⁷² In about 10 to 20 percent of cases, VZV reactivates later in life producing a disease known as shingles. Shingles leads to potential complications like postherpetic neuralgia, zoster multiplex, myelitis, herpes ophthalmicus, or zoster sine herpette.

The clinical manifestations of VZV infection are chickenpox (varicella) and herpes zoster. Chickenpox results from primary VZV infection and occurs in most cases in children under 10 years of age. Immunocompromised children who develop varicella have VZV pneumonia in up to one-third of patients with a fatality rate of about 10 percent.⁷³ Herpes zoster is due to reactivation of latent VZV and is most frequently observed in immunocompromised hosts like, patients with malignancy and on chemotherapy or in recipients of autologous or allogeneic HSCT.^{74, 75}

The diagnosis of VZV infection can be made by a variety of techniques, including viral culture, viral antigen detection, and viral DNA detection. Serologic testing is useful to demonstrate that the patient has had prior primary VZV infection and is therefore harboring the virus in sensory ganglia, but serologic tests are not useful for diagnosis of active VZV infection. PCR technology has revolutionized the diagnosis of VZV, because it is sensitive and rapid. Sometimes, clinical specimen contains inhibitors that may cause false-negative results in PCR assays, signifying the importance of high degree of clinical suspicion and early intervention.

Prevention of chickenpox in immunodeficient patients requires strict isolation from infectious individuals. Following contact with an infected VZV person, the seronegative immunocompromised patients should be given the infusions of VZV hyperimmune globulins within 96 hours of exposure.⁷⁶ Immunization with a VZV vaccine, an additional preventive measure is discussed in the chapter “vaccination of the immunocompromised hosts”.

The drug that changed the clinical scenario for immunosuppressed patients running chickenpox or zoster was acyclovir and is the treatment of choice for these patients.^{77,78}

Localized zoster, seen in patients with mild to moderate immunosuppression, can be treated with high-dose oral acyclovir, valaciclovir or famciclovir with a good efficacy as good as the intravenous therapy. In a randomized study, famciclovir and acyclovir were found to be equally

efficacious and the time to heal the lesions and the rates of secondary zoster dissemination were similar in the two groups.⁷⁹

Following allogeneic HSCT, VZV reactivation may occur for a prolonged period of time. However, long-term antiviral drug prophylaxis is not advisable in allograft recipients, since it only delays the occurrence of zoster and carries the potential for induction of VZV resistance.⁷⁷

The use of a live attenuated VZV vaccine in seronegative immunosuppressed children results in high seroconversion rates and in a reduction of break through varicella and of subsequent herpes zoster.^{80,81} This practice is usually practiced after 12 months in patients with HSCT. In a series of 15 children after HSCT, a VZV vaccine was effective in preventing VZV disease for up to 2 years after immunization.⁸² Among 75 VZV seropositive HSCT recipients randomized to receive an inactivated VZV vaccine or no intervention, immunization was further associated with a better reconstitution of the specific cellular immunity and markedly reduced the severity of zoster.⁸³

FUNGAL INFECTIONS

Fungal infections are one of the very important causes of the mortality and morbidity in the immunocompromised hosts. To discuss each and every fungal infection in detail is beyond the scope of this chapter, so the discussion will involve the epidemiological data and the diagnosis of invasive fungal infection. Only PCP will be discussed here in brief and the Tables 7 and 8 will give the basic management strategies of the common fungal infections and the important facts about the commonly used antifungal agents.

Historically, systemic *Candida* infections have been primarily responsible for invasive fungal infections (IFI) in the immunocompromised hosts but over the last decade mold infections have increased.⁸⁴⁻⁸⁹ The change may be secondary to either the introduction of more accurate diagnostic procedures for diagnosis of IFI or the widespread use of fluconazole prophylaxis. Fluconazole therapy targets many *Candida* spp., but not *Aspergillus* spp. or other molds as given in Table 7.⁸⁷ Yeast infections are less common than mold infections, and *Candida* is still the predominant yeast pathogen. Recently, the emergence of other opportunistic mold pathogens (e.g. *Fusarium* spp. and *Zygomycetes*) has been reported, while infections due to other fungal pathogens remain rare.⁹⁰⁻⁹⁴ In general, the patient's immune status, degree of organ damage (i.e. mucositis or GVHD), microbial exposure (i.e. colonization, journal homepage: environment, and prior infection), older age, type of chemotherapy agent received (i.e. cytarabine) and the use of new drugs (such as monoclonal antibodies) are major factors influencing the likelihood of IFI.⁹⁵⁻⁹⁷ However, deep and prolonged granulocytopenia is the greatest risk factor for IFI. Another key risk

Table 7: Common fungal infections and their management strategies¹¹⁷

<i>Fungal infections</i>	<i>First-line options</i>	<i>Second-line options</i>	<i>Supportive management</i>
Systemic Candidiasis	Voriconazole (PO or IV): 4 mg/kg twice daily in children ≥ 12 yrs Caspofungin (IV): Day 1st—70 mg/m ² Day 2 onwards—50 mg/m ² /day Fluconazole: 8-12 mg/kg daily PO/IV (some authors consider it as an 2nd line)	Amphotericin B lipid complex (IV): 5 mg/kg daily Liposomal amphotericin- B (IV): 3 mg/kg daily IV	Consider the use of G-CSF in neutropenic Steroids to be decreased if possible Remove CVC immediately if possible Do the fundoscopy before the treatment ends in every invasive candidiasis Treatment duration: Uncomplicated candidemia—14 days once blood culture is sterile. Switch over to oral once blood is sterile. Complicated candidemia—duration of treat- ment usually is 4-6 weeks depending upon the condition.
Invasive Aspergillosis	Voriconazole (PO or IV): Age 2-12 yrs: 7 mg/kg twice daily PO or IV Age ≥ 12 yrs: 4 mg/kg twice daily Liposomal amphotericin-B (IV): 3 mg/kg daily (dose escalation to 10 mg/kg not helpful in randomized trials)	Amphotericin B lipid complex (IV): 5 mg/kg daily IV Caspofungin (IV): Day 1st—70 mg/m ² Day 2 onwards—50 mg/ m ² /day	Consider surgery if accessible in skin, sinus, lungs, CNS and soft tissue infections. Consider the use of G-CSF in neutropenic Steroids to be decreased if possible In a unit where we see more of zygomycosis, starting voriconazole might not be the first line. Duration is highly individual based on clinical and culture response. Once clinical response is achieved, IV can be switched over to oral voriconazole.
Antifungal agents as an empirical therapy:			
<i>Indication</i>			
<ul style="list-style-type: none"> • Patient on antibiotics and day 5th of fever <ul style="list-style-type: none"> – Start with liposomal amphotericin-B, dose 1-3 mg/kg daily IV or caspofungin IV, 70 mg/m²/day on day 1 and then 50 mg/m²/daily once 			
Antifungal agents as prophylaxis therapy:			
<i>Indication</i>			
<ul style="list-style-type: none"> • Any patient who is undergoing hematopoietic stem cell transplant or high dose chemotherapy <ul style="list-style-type: none"> – Fluconazole @ dose of 8-12 mg/kg daily, is usually the first agent, or – Voriconazole @ dose of 1 mg/kg daily or – Micafungin @ dose of 1 mg/kg daily or 			
Posaconazole is recommended in patients with HSCT and graft versus host disease @ doses 200 mg three times a day and helps invasive fungal infections. Posaconazole has also shown the overall survival benefit in patients undergoing chemotherapy for AML or MDS.			
Patient on azoles prophylaxis should be given polyene or echinocandin group drugs as these patients usually will be colonized with <i>Glabrata</i> or <i>Krusei</i> species.			

factor for IFI is steroid use; such use modifies phagocyte migration, decreases the antifungal activity of monocytes and macrophages, and enhances the growth of *Aspergillus* spp.⁹⁸ Some reported risk factors are related to specific pathogens. For example, indwelling catheters, prior exposure to broad-spectrum antimicrobial agents, and prior surgery have been well-recognized to facilitate yeast access to the bloodstream and cause invasive candidiasis.⁹⁹

The clinical signs and symptoms of IFI strictly depend on the patient's immune status and the etiological agent and range (i.e. from focal localization to hematogenous dissemination in which almost all organs are involved).¹⁰⁰ During the earliest phase of infection, IFI may be asymptomatic, or fever may be the only clinical symptom

observed. This lack of symptoms may be related in part to the masking of clinical symptoms by treatments (i.e. steroids) administered for the underlying malignancy. The lungs are most frequently affected by *Aspergillus* or other mold infections, and cough, dyspnea, and chest pain is often reported during the early course of pulmonary infections; in advanced stages, severe manifestations (including hemoptysis or pneumothorax) may also occur. *Pneumonia* due to *Zygomycetes* or other molds is clinically indistinguishable from that caused by *Aspergillus*, except for a higher frequency of rhinosinusal localization.⁹⁰ Dissemination to secondary sites of infection (i.e. skin or the central nervous system) may cause additional clinical symptoms.

Table 8: The commonly used antifungal agents ^{118-122*}

Antifungal agents and their mechanism of action:

Drugs acting on cell membrane

Polyenes: Amphotericin-B deoxycholate, amphotericin-B lipid complex, liposomal amphotericin-B and amphotericin-B colloidal dispersion

Triazoles: Fluconazole, itraconazole*, voriconazole and posaconazole

Drugs acting on cell wall

Echinocandins: Caspofungin, micafungin and anidulafungin*

Nucleic acid synthesis inhibitors

Flucytosine

<i>Antifungal agents</i>	<i>Spectrum</i>	<i>Half-life (t_{1/2})</i>	<i>CSF penetration</i>	<i>Significant side effects</i>	<i>Renal adjustment when Cr clearance < 30 ml/mt</i>
Fluconazole	Active Active against most <i>Candida</i> (including <i>Albicans</i> and parapsilosis) but not against <i>C. Krusei</i> and <i>C. Glabrata</i> Active against <i>Cryptococcus neoformans</i> , <i>Coccidioides</i> species and <i>Histoplasma</i> Not active Not active against <i>Aspergillus</i> , <i>Fusarium</i> species, <i>Zygomycetes</i> , <i>Scedosporium</i> and <i>Trichosporon</i>	24 hr	Excellent	Hepatotoxicity Rash + Nausea and vomiting	Not a contraindication but doses should be adjusted
Voriconazole	Active Active against most <i>Candida</i> (including <i>Albicans</i> and parapsilosis) but not against <i>C. Krusei</i> and <i>C. Glabrata</i> Active against <i>Cryptococcus neoformans</i> , <i>Coccidioides</i> species, <i>Histoplasma</i> and <i>Scedosporium apiospermum</i> Active but not a great agent <i>Candida glabrata</i> and <i>Fusarium</i> species Not active <i>Zygomycetes</i> , <i>Scedosporium prolificans</i>	6-24 hr	Excellent	Hepatotoxicity Rash ++ Nausea and vomiting Transient visual disturbances	Oral—can be given IV—contraindicated
Posaconazole	Absolutely same as voriconazole +active against <i>Zygomycetes</i> also	8-24 hr	Poor	Rash ++ Nausea and vomiting Hepatotoxicity very minimal	Oral—can be given No IV preparation available
Amphotericin-B deoxycholate	Active against almost everything except <i>Scedosporium prolificans</i> Active but not a great agent: <i>Aspergillus terreus</i> <i>Candida krusei</i> <i>Fusarium</i> species and <i>Scedosporium apiospermum</i>	Biphasic: Initial phase—24-48 hr; Terminal phase—15 days	Poor in CSF but reaches brain tissue	Common: General— Chills, fever, and headache, pruritus, rash, urticaria, bronchospasm and anaphylaxis Thrombophlebitis Metabolic— Hypokalemia, hypomagnesemia Renal— Renal tubular dysfunction and renal failure Uncommon: CVS— Arrhythmias, flushing, hyper-/hypotension CNS— Delirium, malaise, seizures Hepatotoxicity Hematologic: Anemia, leukopenia, thrombocytopenia (Side effects are minimal with lipid and liposomal preparations)	Contraindicated but the lipid and liposomal preparations can be given with close monitoring

Contd...

<i>Echinocandins</i>	Active	Caspo—	No CSF	Fever	Caspo—no adjustment
Caspo-fungin	All <i>Candida</i> and <i>Aspergillus</i> species	12 hrs	concentration	Rash, thrombophlebitis	needed
Micafungin	Active against <i>Pneumocystis</i>	Mica—18 hrs	but	Hepatotoxicity (doses need to be adjusted)	Mica—no adjustment needed
and Anidulafungin	<i>Carinii</i> but can't be used as a single agent	Anidula-24 hrs	reaches brain	Nausea, vomiting and diarrhea	Anidula—no adjustment needed
	Not Active:			Hypokalemia	
	<i>Cryptococcus neoformans</i> , <i>Coccidioides species</i> , <i>Blastomycosis</i> and <i>Histoplasma</i>			Allergic reactions to infusion	
	<i>Fusarium species</i> , <i>Zygomycetes</i> , <i>Scedosporium</i> and <i>Trichosporon</i>				

* Drugs not approved in pediatric patients

DIAGNOSIS OF INVASIVE FUNGAL INFECTIONS

Laboratory diagnosis of IFI is based on the direct microscopic detection of the etiologic agent in clinical specimens, isolation and identification of the pathogen in culture, or nonculture-based methods involving detection of a serologic response to the pathogen or other markers of its presence (i.e. fungal antigens or metabolites). Microbiological cultures are often insensitive or of limited use. To facilitate the early diagnosis of IFI, the newer fungal markers are galactomannan [GM] and 1,3-beta-D-glucan [BG] assays. GM in a recently published meta-analysis showed an overall sensitivity of 71 percent and specificity of 89 percent for proven cases of IA (invasive aspergillosis) when used for surveillance.¹⁰¹ The measurement of serum BG has also been shown to aid in the diagnosis of fungemia and deep-seated mycoses, including IA. One of the non-culture-based methods for the diagnosis of candidiasis is platelia *Candida*, an ELISA that combines the detection of mannan antigen and antimannan antibodies in serum, allows the earlier diagnosis of *Candida* infection than do blood cultures.¹⁰² A range of polymerase chain reaction (PCR)-based methods has been developed with the goal of offering a highly specific, sensitive, and rapid method of fungal detection and identification. Most of these methods have focused on *Aspergillus* and *Candida* species in various specimen types (i.e. serum, plasma, or BAL fluid), even though pan-fungal PCR amplification technology may be able to detect a broad range of fungal targets.¹⁰³ A recent prospective evaluation of serial PCR assays against or along with GM and chest-computed tomography was carried out in immunocompromised hosts; the PCR method showed acceptable sensitivity and specificity.¹⁰⁴ Recent studies have focused attention on the role of adaptive immunity in the host defense against *Aspergillus* species.¹⁰⁵ In particular, a preliminary report on ELISPOT, *Aspergillus*-specific IFN γ -TH₁, and *Aspergillus*-specific IL-10-producing T-cells (IL-10-TH₂) through an *ex vivo* enzyme-linked immunospot assay showed promising results in the diagnosis and follow-up of IA.¹⁰⁶

Radiological exams are one of the most important diagnostic tools, particularly for pulmonary-localized mold infections.¹⁰⁷ A standard chest X-ray is the first-line

approach, even if it is often not diagnostic. A chest CT-scan is better particularly a high resolution CT-scan (HRCT-scan); with a sensitivity and specificity approaching 100 percent.¹⁰⁸ These scans can demonstrate the presence of the “halo sign,” or the presence of the “air crescent sign,” which usually becomes more prevalent later in the course of the disease.¹⁰⁹ The radiological scans do not allow us to diagnose a specific aspergillosis because of their similarity to other angioinvasive fungi such as *Zygomycetes*, *Fusarium* spp., or *Scedosporium* spp., and this issue makes biopsy necessary to clarify the diagnosis. A study evaluated the utility of CT-guided lung biopsy for the diagnosis of IFI; this study combined Calcolfluor white staining, GM, and PCR on biopsy specimens. This combination resulted in the fast and reliable identification of the fungus with a specificity and sensitivity of 100 percent. However, performing such a detailed and invasive diagnostic study is very critical, because of the many contraindications for the performance of an invasive procedure in these immunocompromised hosts (i.e. thrombocytopenia and hemodynamical instability).¹¹⁰

PNEUMOCYSTIS JIROVECI PNEUMONIA

Historically, *pneumocystis jiroveci* pneumonia is (PCP) known to be associated with HIV but this in one of the significant cause of morbidity and mortality in immunocompromised children with hematological malignancies, brain tumors, and those undergoing HSCT. A recent Cochrane review recommended PCP prophylaxis as an important management strategy in these immunocompromised children¹¹¹ and three times a week is now the acceptable protocol for the prophylaxis.

P. jiroveci infection commonly presents with tachypnea, nonproductive cough and fever, but the severity can vary. There is usually a subacute diffuse pneumonitis and chest X-ray changes can be subtle. These often take the form of bilateral diffuse interstitial changes, although lobar, miliary or nodular changes can be seen. HRCT may show ground glass attenuation, consolidation, nodules, thickening of interlobular septa and thin walled cysts. Mortality ranges between 5 and 40 percent, if treated, but can reach

nearly 100 percent if left untreated. Identification of PCP can be difficult. Definitive diagnosis depends on identifying the organism in respiratory tract secretions or lung tissue, usually from tracheal secretions, bronchial secretions or from lung biopsy. More recently, PCR technology has been developed for identifying PCP from secretions. In a review of children diagnosed with severe combined immune deficiency (SCID) treated at a supraregional center, 10 out of 50 were identified as having PCP. One was diagnosed on BAL prior to transfer to the supraregional center, one was diagnosed on nasopharyngeal secretions and BAL, seven were diagnosed on BAL alone, and in one diagnosis was not made until lung biopsy was performed.¹¹²

Recommended first line PCP treatment is high dose cotrimoxazole. This can, however cause a number of adverse effects, for example, neutropenia, anemia, renal dysfunction, rash, vomiting and diarrhea. Those that cannot tolerate cotrimoxazole or those that have not improved after 5 to 7 days of treatment should be changed to a different agent. Choices include pentamidine, atovaquone, clindamycin/ primaquine or dapsone, but experience with these agents in children is limited.

In children that cannot tolerate cotrimoxazole, either dapsone or aerosolized pentamidine can be used. Corticosteroids should be given as an adjunctive therapy in moderate and severe PCP. A number of studies have shown a reduction in acute respiratory failure, decreased need for ventilation and decreased mortality.¹¹³⁻¹¹⁵ A recent Cochrane review supports the use of corticosteroids in HIV-infected patients with PCP, especially in those with substantial hypoxaemia.¹¹⁶

SUMMARY

Infections in immunocompromised children are difficult both in diagnosis and management. Organisms which are usually mild in an immunocompetent host can have devastating effects in an immunocompromised child. Clinical diagnosis is often very difficult and establishing a microbiological diagnosis is rather difficult. Clinical suspicion holds the key for early and appropriate management. Negative tests should not be taken to be reassuring if there is clinical suspicion and it may be necessary to look further and more closely. Once an infection is identified, it must be acted upon quickly as delay may be disastrous. Treatment of any infection in an immunocompromised child is likely to be more intense and prolonged than in a child with a fully functioning immune system. It is also important to consider prophylaxis for specific patient groups in specific situations (e.g. post-HSCT) and each unit should have defined policies and guidelines to follow for these patients. To conclude, when dealing with an immunocompromised child, for whatever reason, if there is any suspicion of infection, think about early intervention.

Health Care-Associated Infections in Pediatric Intensive Care Unit

Dhiren Gupta, Sheikh Minhaj Ahmed

INTRODUCTION

Pediatric Intensive Care Unit (PICU) related health care associated infection (HAI) is defined as any infection that was not present or incubating at the time of PICU admission but occurred at 48 hours or more after admission to the PICU.¹ As a better reflection of the diverse health care settings currently available to patients, the term health care-associated infections replaced old ones such as nosocomial, hospital-acquired or hospital-onset infections. Most infections that become clinically evident after 48 hours of hospitalization are considered hospital-acquired. Infections that occur after the patient is discharged from the hospital can be considered health care-associated if the organisms were acquired during the hospital stay.

Pediatric intensive care units (PICUs) differ from adult intensive care units (ICUs) in a number of ways, apart from the age of their patients. First, they are usually multidisciplinary.² Second; they frequently lack the physical barriers between patients now commonly present in adult ICUs. Third, fewer children than adults in ICUs have chronic or degenerative organ system disorders;³ and probably the majority of children in PICUs will, if successfully treated, return to a normal productive life. Nosocomial infections represent an important cause of morbidity and mortality in this population.⁴

Health care associated infection (HAI) rates vary widely between different patient populations, with the highest rates usually occurring in pediatric intensive care units (PICUs) and neonatal intensive care units (NICUs). These infections often lead to increased morbidity and mortality. Furthermore, prolonged need of hospitalization due to HAIs may give rise to substantial additional costs.

Patients in the pediatric intensive care unit (PICU) are particularly susceptible to HAI in part due to the use of invasive devices and procedures in this critically ill

population.⁵ Incidence of nosocomial infections due to antibiotic-resistant organisms is increasing, with specific examples in the pediatric intensive care unit (PICU).⁶⁻⁹ The prevalence of hospital-acquired or nosocomial infections in pediatric patients ranges from 6 to 12 percent in the PICU and 10 to 25 percent in the NICU.¹⁰⁻¹⁵

SOURCES AND MODES OF TRANSMISSION

Health care associated infections can be caused by endogenous or exogenous organisms. Endogenous infections usually occur as a result of health care-associated interventions (e.g. surgical procedures or the insertion of vascular catheters or other indwelling devices) by colonization and subsequent infection with microorganisms from the hospital environment due to immunosuppression, or by normal flora altered through antimicrobial therapy. Exogenous infections result from the transmission of organisms from the hospital environment.

Pathogens-associated with HAIs in hospitalized children differ from those in adults. Gram-negative bacilli, including ESBL and other multidrug-resistant isolates, may be more frequent than MRSA and VRE in many PICUs and NICUs. Patients who are transferred from chronic care facilities may be colonized with resistant gram-negative bacilli at the time of admission to the PICU.

RISK FACTORS FOR HEALTH CARE-ASSOCIATED INFECTIONS

The identification of risk factors enables the development of preventive strategies. Most PICUs care for a heterogeneous population of children of varying age, diagnosis, and underlying illness, ranging from infants with congenital anomalies to adolescents with multiple traumas. Consequently, even patients admitted to the same PICU may differ substantially in their risk for HAI.

A systematic review of observational studies on risk factors for health care-associated infection in pediatric intensive care units,¹⁶ revealed the risk factors for a first episode of health care-associated infection included: post-operative period, greater severity upon admission based on the PRISM or PRISM III, invasive procedures, the use of antimicrobial agents, parenteral nutrition, remaining more days or more than seven days in the pediatric ICU. Reducing health care associated infections requires best practice in clinical care, consistently and reliably. However, reducing HAI also requires that other issues, beyond best practice at the point of care, be addressed, e.g. isolation practice, bed occupancy, hospital policies, compliance, monitoring, surveillance, screening, antibiotic stewardship, bed management, patient pathways, bed moves, staffing levels, training, expertise, leadership, information management, environment and design, management systems, laboratory service, equipment, devices, cleaning standards and contracts, decontamination, procurement, accountability, risk management, resource allocation, etc. The prevention of infection is a core component of patient safety, and achieving patient safety in acute health care requires more than individual carefulness.¹⁷

TYPES OF HEALTH CARE-ASSOCIATED INFECTIONS

Catheter-Related Bloodstream Infections

Stable vascular access is essential to the management of the critically ill patient. Central venous access devices (CVADs) provide reliable venous access for short-term and extended infusion of intravenous chemotherapy, bi-therapy, and supportive therapies during the diagnostic phase, treatment phase, or the palliative phase of their disease course. Most patients will have at least one central venous catheter, and many may have an arterial catheter as well. An increasing number of patients will have some type of tunneled, cuffed central venous catheter or some type of subcutaneous central venous port.

The relative risk of bloodstream infection caused by various intravascular devices ranges widely, depending on the length of the device, the type of device, the patient population, the techniques used in insertion, the frequency of manipulation, and the time they have been in place.^{18,19}

The highest risk is with short-term, noncuffed central venous catheters, in the range of 2 to 5 per 1,000 catheter days, and is especially high with temporary hemodialysis catheters. Arterial catheters used for hemodynamic monitoring and peripherally inserted central venous catheters used in hospitalized patients seem to have a risk of catheter-related bloodstream infection (2–3 per 1,000 catheter days) similar to conventional subclavian, internal jugular, or femoral short-term, noncuffed central venous

catheters. In contrast, the risk of bloodstream infection with small, peripheral intravenous catheters is 0.1 cases per 1,000 catheter days. With good care, surgically implanted ports are associated with a much lower risk of bacteremia/fungemia than temporary percutaneous catheters, approximating 0.2–1 per 1,000 catheter days.¹⁸

Risk factors for development of CR-BSI have been recognized in PICU patients includes; Extracorporeal life support, presence of multiple intravascular devices, and longer duration of intravascular device use were associated with an increase in rate and risk of developing CR-BSI in PICU patients. Use of arterial catheter and packed red blood cell transfusion, as well as the presence of a genetic syndrome, were identified by multivariate analysis as risk factors for nosocomial primary blood stream infection (BSI) in PICU patients.²⁰

Published guidelines from the CDC have set criteria²¹ for diagnosing bloodstream infections that involve intravascular catheters. A catheter-related bloodstream infection is either a bacteremia or fungemia documented with at least one peripherally obtained blood culture that is obtained from a vein and not a catheter. Clinical evidence of an infection, including a host response, must be present that cannot be attributed to any source other than the catheter.

The growth of an organism in the bloodstream must be documented by (a) positive semiquantitative or quantitative cultures of a catheter segment with an organism identical in species and antibiogram as isolated from a peripheral blood culture, (b) simultaneously drawn peripheral and line quantitative blood cultures with greater than a 5:1 ratio in catheter blood versus peripheral blood colony counts, or (c) a differential in timing of culture positivity of >2 hrs between the catheter and peripheral blood culture, where the catheter culture is positive first.

A catheter-associated bloodstream infection has less rigorous criteria and requires the presence of a central line being in place during the 48 hrs prior to the drawing of the positive culture and compelling evidence that the infection is related to the line. This definition is helpful for surveillance but can overestimate the true incidence of bloodstream infections.²¹

Coagulase-negative staphylococci are the most common cause of pediatric health care related bloodstream infections, accounting for 20 percent to nearly 50 percent of isolates. Gram negative bacteria account for 25 percent of PICU health care related bloodstream infections. *S. aureus* and *Candida* spp. are responsible for ~10 percent each throughout the pediatric age range. Other organisms that cause health care related bloodstream infections are dependent upon the age of the child and other clinical factors. Hemolytic streptococci are more prevalent in the neonatal population, causing 8.5 percent of the hospital-acquired infections in this age group. Bimodal peak is reported for enterococcal infections seen in infants and

patients 13 to 65 years of age, with 9.4 percent and 8.5 percent of isolates, respectively. At 7.3 percent, *Klebsiella* spp. are the third most common isolates behind coagulase-negative staphylococci and *S. aureus* in the pediatric oncology population.²²⁻²⁴

Empiric therapy for CR-BSI should consist of an agent to cover gram-positive and an agent to cover gram-negative organisms, based on local antimicrobial resistance patterns. The 2009 IDSA guidelines for intravascular catheter-related infection provides an extensive review of the management of CR-BSIs in adult and pediatric populations. Vancomycin is recommended for empiric gram-positive therapy in health care settings with known high rates of MRSA.

Empiric coverage for gram-negative bacilli should be based on local susceptibility patterns and the severity of disease. Fourth-generation cephalosporins, carbapenems, or β -lactam/ β -lactamase combinations are recommended because of their coverage of *Pseudomonas* sp. An aminoglycoside may also be added empirically, and is specifically recommended for neutropenic patients, those who are severely ill and those with sepsis, in addition to patients known to be colonized with multi-drug resistant gram-negative organisms. Patient with femoral lines are recommended to have gram-positive, gram-negative coverage and well as coverage for *Candida* sp. Culture results should be used to de-escalate antimicrobial therapy when known.²⁵

The duration of antimicrobial therapy for CR-BSI vary by host and pathogen. In most cases, it is recommended that catheters that are infected be removed and that the patient receive intravenous antimicrobial therapy for 7 to 14 days, depending on the isolated pathogen. Duration of therapy is based on the day of the first negative blood culture result. A longer duration of therapy is recommended for CR-BSI caused by *S. aureus*. Even longer durations of antimicrobial therapy are recommended for patients with persistent bacteremia or fungemia due to supportive thrombophlebitis, endocarditis, osteomyelitis or other severe infections. Coagulase-negative *Staphylococcus* sp. (CONS) may be treated from 5 to 7 days after catheter removal.²⁵

VENTILATOR-ASSOCIATED PNEUMONIA

Pneumonia is the second most common cause of infection acquired in the ICU and a ubiquitous cause.^{26,27} In an ICU, it can be difficult to determine whether fever is due to pneumonia when patients commonly have other noninfectious processes producing abnormal chest radiographs and gas exchange (i.e. congestive heart failure, atelectasis, acute respiratory distress syndrome).

Many patients in an ICU are intubated and sedated, cannot cough, and have other reasons for abnormal secretions. In addition, immunocompromised patients, such as solid organ transplant recipients, may have severe

pneumonia without fever, cough, sputum production, or leukocytosis.^{28,29}

Ventilator-associated pneumonia (VAP) is diagnosed based on criteria from the US Centers for Disease Control and prevention (CDC).²⁹ However, there is no gold standard for the diagnosis of VAP in children or adults. In general, VAP criteria include a new or progressive radiographic infiltrate, consolidation, cavitations or pneumatocoles (in infants under 12 months of age) that has persisted for at least 2 days as well as two of the following: a temperature above 38.5°C or below 35.0°C, a leukocyte count above 10,000/mm³ or less than 5,000/mm³, purulent sputum, or isolation of pathogenic bacteria for endotracheal tube (ETT) aspirates.²⁹

Age criteria for those infants under 1 year and children greater than 1 year but less than 12 years of age have also been created.^{30,31} Specimens obtained from the lower airway for respiratory culture are preferred. The use of bronchoalveolar lavage (BAL), nonbronchoscopic-BAL or protected specimen brush samples are safe and aid in the acquisition of an adequate of sample for respiratory culture in suspected pediatric VAP patients.

Although the main contributing factor for VAP development is mechanical ventilation, risk factors for the development of VAP have been studied and include the presence of a genetic syndrome, reintubation, transport out of the PICU, use of neuromuscular blockade agents, and immunosuppression.^{32,33} Other risk factors for the development of VAP include female gender, postsurgical, the presence of enteral feedings, and the use of narcotic medications.³⁴

The use of H2-blocking agents may allow for enteric bacteria to colonize the upper gastrointestinal tract and may predispose pediatric patients to VAP.³² Other medications that may contribute to the development of VAP include steroids and total parenteral nutrition (TPN).³³ Narcotic agents have also been associated with VAP.³⁴

Single agents that may be efficacious for VAP include carbapenems, cefepime, or piperacillin-tazobactam. Fluoroquinolones may also be used for monotherapy for VAP in certain situations. There is no specific recommendation for VAP treatment duration of therapy. Short treatment courses of 5 to 7 days may be appropriate in those patients with uncomplicated disease,³⁵ but longer treatment courses may be warranted for critically ill children infected with MDR organisms (MDROs).

Ventilator Bundles in the Management of VAP

The prevention of VAP bundle of care, was developed for adult patients, but has been applied to pediatric practice as well. Following are the interventions for, prevention of VAP bundle of care:

- Conduction of active surveillance for VAP
- Adherence to hand hygiene guidelines

- Maintenance of patients in a semirecumbent position (30-45 degree head of bed elevation)
- Daily sedation vacation and assessment of readiness to extubate with use of weaning protocols
- Regular oral care with an antiseptic solution
- Use of noninvasive ventilation whenever possible, minimizing the duration of ventilation
- Preference for orotracheal intubation over nasotracheal intubation
- Maintenance of endotracheal cuff pressure of at least 20 cm H₂O
- Removal of condensate from ventilator circuits, keeping the ventilator circuit closed during condensate removal
- Changing of the ventilator circuit only when visibly soiled or malfunctioning
- Avoidance of gastric overdistention
- Avoidance of histamine receptor 2 blocking agents and proton pump inhibitors
- Use of sterile water to rinse reusable respiratory equipment.

There are some limitations in pediatric age group which limits the generalization of bundle care applicable in adult age group:

- *Head end elevation* >30° is challenging in the infant due to neck bending.
- *Daily sedation vacation*: Difficult in pediatrics due to high risk of unplanned extubation.
- *Use of cuffed endotracheal tubes* may not be possible in all cases.

Chlorhexadine mouthwash has been shown to significantly reduce the incidence of VAP.³⁶ Early enteral feeding, a favored practice in pediatric, is recognized as contributing to improved patient outcomes and morbidity as well as providing some protection against the development of stress ulcers.

Urinary Tract Infections

Urinary catheterization is a routine procedure in an intensive care unit for monitoring urine output of critically ill patients. Catheter-associated bacteriuria or candiduria usually represents colonization, is rarely symptomatic, and is rarely the cause of fever or secondary bloodstream infection,³⁷ even in immunocompromised patients,³⁸ unless there is urinary tract obstruction, the patient has had recent urologic manipulation or surgery, or is granulocytopenic.^{39,40}

The traditional clinical signs and symptoms (dysuria, urgency, pelvic or flank pain, fever or chills), that correlate well with significant bacteriuria in noncatheterized patients are rarely reported in ICU patients with documented catheter-associated bacteriuria or candiduria of >10⁵ colony-forming units (cfu)/ml.

The most common complication of the use of bladder catheterization is infection. Cystitis, pyelonephritis and secondary BSI can occur from catheter-associated urinary tract infection (UTI). The most commonly isolated pathogens are enteric gram-negative organisms as well as other perineal flora including *Enterococcus* sp. and *Candida* sp. Patients may or may not have pyuria.

The basic management of catheter-associated UTI is the removal of the catheter, when possible. Patients with complications of UTI such as pyelonephritis or BSI require systemic antimicrobial therapy. Currently, there is no consensus on duration of therapy for urinary catheter-associated UTI.⁴¹

Childhood Tuberculosis

Varinder Singh, Ankit Parakh

INTRODUCTION

Not long ago tuberculosis used to be a major public health problem practically all over the world. In recent years it has been brought under control in the affluent countries of the west to an extent that it has ceased to be a health hazard. However, it continues to be a major public health problem and a killer in developing countries like India.

By itself, tuberculosis is one of the major infections affecting children worldwide. Young children carry the greatest burden of disease. They are not only most likely to develop disease after infection but also more prone to develop extra pulmonary and severe disseminated disease. Also those with latent infection become the reservoir for future transmission following disease reactivation in adulthood. Tuberculosis, on the whole, has better prognosis in children than the young adults and children with this disease are far less frequently infectious than older individuals, but the relevance of childhood tuberculosis lies in the fact that the most serious manifestation of tuberculosis in older people has its beginning in childhood when most infections take place in the developing countries. Childhood tuberculosis has been relatively neglected and there is very little information about the burden of disease in children worldwide. According to estimates, in industrialized countries childhood TB constitutes about 7 percent of all TB cases and the disease is much more prevalent in resource poor developing countries (15-40% of all TB). In India, 1.5 percent of about 2,45,000 new smear-positive cases on DOTS were aged 0 to 14 years and pediatric cases made up 3 percent of total load of new cases registered. However, these figures are likely to be substantially lower than the true burden of disease. It has been estimated that 10 percent of the actual total TB caseload in India is amongst children.¹

The rate of infection does not seem to be dependent *per se* on race, religion and socioeconomic conditions. It

depends entirely on opportunities of infection. Since poor people live ordinarily in congested localities, the higher infection among them are not so much due to poverty than overcrowding resulting in increased opportunities of infection.

ETIOPATHOGENESIS

Tuberculosis is a chronic infectious disease caused by *Mycobacterium tuberculosis*. Primary infection can occur when a previously uninfected child inhales even a single infectious aerosol droplet (containing as little as five bacilli) that penetrates into a terminal airway. The risk of a person developing disease once infected is determined by various factors including age, recently acquired infection, the nutritional and immune status of the child, genetic factors, the virulence of the organism and the size of infecting dose and inter current infections such as measles, pertussis. It has been estimated to be 5 to 10 percent in adults, 15 percent in adolescents, 24 percent in children 1 to 5 years of age and as high as 43 percent in infants. Primary infection before 2 years of age frequently progresses to serious disease within the first 12 months without significant prior symptoms. However, for infants the time span may be as short as 6 to 8 weeks. Also about 25 to 30 percent of children with tuberculosis have extra-pulmonary presentation in comparison to adults in whom about 15 percent have extrapulmonary presentation.² HIV coinfection can further increase the risk of developing the disease across all age groups.

PRIMARY PULMONARY DISEASE

Entry and establishment of bacilli in human body constitutes infection. It usually takes 6 to 8 weeks for the establishment and manifestation of infection. Infection is indicated by a positive reaction to a tuberculin skin test

(Mantoux test). Primary infection is an infection occurring for the first time in susceptible individuals who are exposed to tubercle bacilli. Droplet nuclei that are inhaled into the lungs, are so small ($<5\ \mu\text{m}$) that they avoid the muco-ciliary defences of the bronchi and lodge in the terminal bronchiole or alveoli of the lungs. Subsequently, the bacilli multiply and invade the hilar lymph nodes through the lymphatics. The subpleural lung lesion, lymphangitis and hilar adenopathy together constitute a *primary complex*. In most cases, the host's immune defences overcome the primary infection, which generally passes unnoticed. The initial parenchymal inflammation usually is not visible on chest radiograph, but a localized, nonspecific infiltrate may be seen before the development of tissue hypersensitivity. About 70 percent of lung foci are subpleural, and all lobar segments are at equal risk for initial infection. The hallmark of primary tuberculosis in the lung is the relatively large size of the regional lymphadenitis compared with the relatively small size of the initial lung focus. The hilar lymph nodes can continue to enlarge compressing the regional bronchus and causing obstruction. The usual sequence is hilar lymphadenopathy, focal hyperinflation, and then atelectasis. Endobronchial TB occurs when the infected lymph nodes erode into a bronchus. Enlargement of lymph nodes may result in signs suggestive of bronchial obstruction (partial or complete bronchial obstruction). Usually, it is the result of deposition of caseous material within the lumen.³

The symptoms and physical signs of primary pulmonary TB are comparatively less considering the degree of radiographic changes often seen. Up to 50 percent of infants and children with radiographically moderate to severe pulmonary TB have no physical findings. Infants are more likely to experience signs and symptoms. Nonproductive cough and mild dyspnea are the most common symptoms. Systemic complaints such as fever, night sweats, anorexia, and decreased activity occur less often. Some infants and young children with bronchial obstruction have localized wheezing or decreased breath sounds.

PROGRESSIVE PRIMARY PULMONARY DISEASE

As tuberculosis progresses, infected material may be spread via the airways into other parts of the lungs, causing a patchy bronchopneumonia. Erosion of a parenchymal focus of tuberculosis into a blood or lymph vessel may lead to dissemination of the organism and a "miliary" (evenly distributed small nodules) pattern on the chest film. Disseminated tuberculosis can occur in primary disease and may be an early complication of tuberculosis in children (both immunocompetent and immunocompromised).

A rare but serious complication of tuberculosis in a child occurs when the primary focus enlarges steadily and develops a large caseous center. Liquefaction can cause

formation of a primary cavity associated with large numbers of tubercle bacilli. The enlarging focus can slough necrotic debris into the adjacent bronchus, leading to further intrapulmonary dissemination. Significant signs or symptoms are common in locally progressive disease in children. High fever, severe cough with sputum production, weight loss, and night sweats are common.

REACTIVATION TUBERCULOSIS

Tuberculosis that develops as a result of endogenous reactivation of latent infection usually causes abnormalities in the upper lobes of one or both lungs. Cavitation is common in this form of tuberculosis. The most frequent sites are the apical and posterior segments of the right upper lobe and the apical-posterior segment of the left upper lobe (*Simon foci*). This form of tuberculosis is rare in childhood but can occur in adolescence. This form of disease usually remains localized to the lungs, because the established immune response prevents further extrapulmonary spread.

Older children and adolescents with reactivation tuberculosis are more likely to experience fever, anorexia, malaise, weight loss, night sweats, productive cough, hemoptysis, and chest pain than children with primary pulmonary tuberculosis. However, physical examination findings usually are minor or absent, even when cavities or large infiltrates are present. Most signs and symptoms improve within several weeks of starting effective treatment, although the cough can last for several months.

PLEURAL TUBERCULOSIS

There are two mechanisms by which the pleural space becomes involved in tuberculosis. The difference in pathogenesis results in different clinical presentations, approaches to diagnosis, treatment, and sequel. Early in the course of a TB infection a few organisms may gain access to the pleural space (from a subpleural pulmonary focus or caseated lymph node) and, in the presence of cell-mediated immunity, cause a hypersensitivity response. Tuberculous pleural effusion is uncommon in children <6 yr of age and rare in children <2 yr of age. Effusions are usually unilateral but can be bilateral. Commonly, this form of tuberculous pleuritis goes unnoticed, and the process resolves spontaneously. In some patients, however, tuberculous involvement of the pleura is manifested as an acute illness with fever and pleuritic pain. If the effusion is large enough, dyspnea may occur, although the effusions generally are small and rarely are bilateral. In approximately 30 percent of patients there is no radiographic evidence of involvement of the lung parenchyma; however, parenchymal disease is nearly always present. Often the radiographic abnormality is more extensive than would be suggested by physical findings or symptoms. The TST is positive in only 70 to 80 percent of cases.

The second variety of tuberculous involvement of the pleura is empyema. This is much less common than tuberculous pleurisy with effusion and results from a large number of organisms spilling into the pleural space, usually from rupture of a cavity or an adjacent parenchymal focus via a bronchopleural fistula. A tuberculous empyema is usually associated with evident pulmonary parenchymal disease on chest films and air may be seen in the pleural space. In the absence of concurrent pulmonary tuberculosis, diagnosis of pleural tuberculosis requires thoracentesis and, usually, pleural biopsy.

Diagnostic thoracentesis usually reveals yellow fluid and only occasionally tinged with blood. The typical fluid shows a exudative lymphocytosis although in the early part polymorphonuclear cells might predominate. The glucose concentration may be low or in the low-normal range (20-40 mg/ dl). AFB is usually negative. Cultures of the fluid are positive in <30 percent of cases. Pleural biopsy using a Cope's or Abraham's pleural biopsy needle is useful in doubtful cases and usually would show caseating granulomas (sometimes positive AFB stain or culture).

EXTRAPULMONARY TUBERCULOSIS

Lymphadenitis

Superficial lymphadenitis (responsible for 44 to 67 percent of cases): It is the most common site of extrapulmonary TB followed by pleural, meningeal, osteoarticular and miliary TB in varying frequency depending on the patient population. It usually affects the anterior cervical and submandibular nodes. Firm, nontender or minimally tender enlarged lymph nodes, without generalized symptoms is the most common presentation. In advanced disease, matting, adherence to the overlying skin with dark discoloration of the skin, and subsequent sinus formation may occur.

Tubercular Meningitis

Tubercular meningitis (TBM) is the most feared complication of tuberculosis and is most common in the younger children— 0 to 4 years of age accounting for 80 percent of meningitis cases. The clinical presentation is usually indolent, with symptoms present 1 to 4 weeks before diagnosis. The most common presenting symptoms are fever, vomiting, lethargy, headache, and seizures. Seizures are especially common in children less than 2 years of age. Physical findings include nuchal rigidity, cranial nerve palsies and hemiparesis. The clinical course is divided into stages that have prognostic significance: Stage I (nonspecific symptoms such as fever, irritability, headache, sleepiness, or malaise with no focal neurologic findings), Stage II (nonspecific symptoms with neurologic findings), and Stage III (marked decrease in mental status with neurologic findings). Most cases with stage I will have intact

recovery while stage III cases have a significant mortality and morbidity.

Miliary TB

Miliary TB occurs following hematogenous dissemination with spread to two or more organs. It may occasionally present acutely, but, in most cases, weeks of fever, cough, weight loss, anorexia and malaise are present before diagnosis. Hepatosplenomegaly and generalized lymphadenopathy develop in 50 to 70 percent of cases. Bilateral diffuse micronodular pulmonary consolidations develop in 90 percent of cases and manifest as respiratory distress, diffuse rales, or wheezing. Military and meningeal tuberculosis frequently present together, especially in children less than 5 years of age.

Osteoarticular TB

Osteoarticular TB accounts for 1.4 percent of all cases of pediatric TB and 5.9 percent of cases of extrapulmonary TB in children. The vertebrae, followed by knee, hip, and elbow are the bones most commonly affected. Presenting signs and symptoms may include localized inflammation, pain, swelling, fever, decreased movement and limited range of motion of the affected bone or joint. Radiographic evidence of spondylitis, arthritis, and osteomyelitis may occur and chest radiograph abnormalities may be seen in up to 50 percent of cases.

Abdominal Tuberculosis

Abdominal tuberculosis may present as localized disease such as mesenteric lymphadenopathy, intestinal disease, peritoneal involvement or systemic disseminated disease presenting as hepatosplenomegaly.

Additional presentations, such as tuberculosis of the gastrointestinal tract, eyes, genitourinary tract, pericardium, skin, larynx or middle ear rarely occur in children.

DIAGNOSIS

Diagnostic difficulties pose the greatest challenge to childhood tuberculosis management. Main impediments to the accurate diagnosis of active tuberculosis are the paucibacillary nature of the disease, nonspecific clinical presentation and the fact that young children seldom produce sputum. Thus bacteriological diagnosis, which is gold standard for diagnosing TB, is difficult in children. The diagnosis of TB is, therefore, dependent on combination of clinical history and presentation, history of contact with a known TB case and result of TST and radiology. The two basic approaches to the diagnosis of TB: the direct approach including detection of *Mycobacteria* or its products and the indirect approach including measurements of humoral and cellular responses of the host against TB are discussed further.

Direct Approach in Diagnosis

Mycobacterial Detection and Isolation

Despite the difficulties of bacteriological diagnosis, a sincere and active effort must be made in all suspects. The sensitivity of smears for identification of *M. tuberculosis* is low (in the range of 25-30%) but specificity is very high (in the range of 90-99%). Pediatric TB is usually paucibacillary, unless there are visible cavities in the lung and further there is a difficulty with specimen collection as children do not expectorate or bring up sputum and also because they may have extrapulmonary TB, where access to appropriate body specimen may not be easy or feasible.

Specimens to be used:

- *Sputum and induced sputum:* Unless endobronchial tuberculosis is present, children <6 years of age usually do not have a cough deep enough to produce sputum for analysis. However, where feasible, sputum analysis should be done. Sputum induction by nebulized hypertonic saline has been reported to induce a higher yield of *M. tuberculosis* than gastric washings. However, feasibility of this technique has not been tested outside hospital settings and the infection control procedures must be strictly adhered to.
- *Gastric aspirates:* First morning gastric aspirates have traditionally been the best clinical specimens to obtain in young children. These aspirates may be positive for *M. tuberculosis* in 30 to 50 percent of all cases and in as many as 75 percent of infants. Hospitalization is not necessary to obtain gastric aspirate specimens from children with suspected TB as it can be done after 4 to 6 hours of fasting on an OPD basis. Traditionally 3 consecutive gastric aspirates/lavages have been used. Reports now suggest that two or even one gastric aspirate may yield optimal results. According to the revised WHO and RNTCP policies, 2 instead of 3 sputum samples are now considered sufficient to screen possible pulmonary tuberculosis in adults. Following suit, the same is being suggested for gastric aspirates.
- *Bronchoalveolar lavage (BAL):* The evidence so far is balanced between simple GAs and BAL while the ease would certainly tilt the balance in favor of GAs. Bronchoscopy, however, can provide direct visual clues to diagnosis in form of caseation, etc.
- *Others:* Depending on the location of the disease lymph node tissue, pleural/ascitic fluid, cerebrospinal fluid, bone marrow, liver, urine may be undertaken.

Direct Smear and AFB Staining of Specimens

Microscopy: Smear examination remains the simplest and the most rapid test currently available for the diagnosis of AFB by Ziehl-Neelsen stain or its modifications. The advantages are that it is rapid, cheap, simple, no infrastructure required, can be made available in field

setting. The major limitation is that it requires at least 5×10^3 bacilli per ml of sputum and it requires trained staff (observer dependent). As a significant proportion of childhood TB is paucibacillary, the utility of this test is further limited in children. Fluorescence microscopy has several advantages over light microscopy using ZN staining and is widely used in most developed nations. Fluorochrome staining procedure used with FM is not only simpler than that of ZN staining but is also has about 10 percent greater sensitivity for detecting AFB in patient specimens.⁴ As FM can be examined at a lower magnification than ZN (20-40 vs 100 \times), slides are read more quickly and efficiently with FM. It has been estimated that using FM may take up to 75 percent less time than ZN.⁴ Unfortunately, FM was not so popular so far in resource poor settings due to its high capital and maintenance costs, limited lamp life, and need to keep away from dusty environments. User acceptance was also poor due to production of UV light and heat and the requirement to work in a dark room for long hours. Recently, the low-cost, ultra-bright light-emitting diodes (LEDs) have replaced the mercury vapor lamps in the FM and made it possible to use as side laboratory equipment.

Mycobacterial Culture

Mycobacterial culture remains the gold standard for detection and drug susceptibility testing (DST). Traditionally, culture on an egg-based solid media, known as Lowenstein-Jensen medium, may take as long as 4 to 6 weeks because of the slow growth and additional 4 weeks for drug susceptibility testing. Liquid culture systems (BACTEC and MGIT) offer a more sensitive and rapid alternative to conventional solid culture and may detect growth in 1 to 3 weeks.^{5,6}

BACTEC system: This radiometric technique is specific for *Mycobacterium* growth, where in ^{14}C labeled palmitic acid in 7H12 medium is used. This system detects the presence of mycobacteria based on their metabolism rather than their visible growth. When the ^{14}C labeled substrate present in the medium is metabolized, $^{14}\text{CO}_2$ is produced and measured by the growth index value (GI). This method can detect growth as early as in 5 to 10 days though a sample is considered negative if only there is no growth even after 6 weeks of incubation.

Compared to the conventional culture and drug susceptibility testing methods BACTEC method is faster (87% of the positives being obtained by 7 days and 96 percent by 14 days) and it showed a good correlation in drug susceptibility tests with conventional Solid LJ media. However studies have failed to show an increased efficiency in detecting smear negative cases.

MGIT 960 Mycobacteria detection system: It is a nonradiometric automated system for the growth and detection of

mycobacteria with a capacity to incubate and continuously monitor 960 mycobacteria growth indicator tubes (MGIT) every 60 minutes for increase in fluorescence. Growth detection is based on the AFB metabolic O₂ utilization and subsequent intensification of an O₂ quenched fluorescent dye contained in a tube of modified MGIT. Using paired specimens, BACTEC 460 and MGIT 960 systems took about 13.4 versus 15.5 days for *M. tuberculosis* isolation respectively. MGIT 960 system exhibits greater potential as a rapid, accurate and environment friendly method.⁶

The yield of mycobacteria is high when the samples are repeated, in extensive pulmonary disease and in infants, where it can be up to 70 percent. Availability of LED fluorescent microscope now is expected to make Auromine staining and smear examination simpler, faster with an improved yield. While neutralization of the aspirate has generally been recommended before transporting the sample to the laboratory for culture, the experience with newer liquid culture methods has shown a higher risk of contamination due to this.

Genotypic Methods

Genotypic methods are available with newer modifications for the diagnosis of TB as an alternative for smear microscopy. *Polymerase chain reaction (PCR)* methodology is rapid; results are available within a day of DNA extraction from the sample. The most common target used in the PCR is IS6110. A variety of PCR methods have been described in the search for a sensitive and reliable screening test for TB in clinical specimens. Species-specific and genus-specific PCR methods are being used with various targets and modifications of PCR.

Real time PCR: Realtime PCR is a significant advance which can detect the presence of amplified nucleic acid target in a closed system without having to resort to cumbersome gel—or ELISA-based detection. Thus the risk of cross-contamination of samples by amplified DNA from previous positive samples is precluded.

GeneXpert® MTB/RIF system developed by Cepheid (CA, USA) together with the Foundation for Innovative New Diagnostics uses a closed real time PCR system packaged inside a cartridge. This system is one of the first point-of-care PCR test which requires minimal manipulation of sample and operator training. The test not only identifies *M. Tb* but can also simultaneously identify rifampin resistance using a region of the *rpoB* gene of MTB that is responsible for 95 percent of rifampicin resistance. Preliminary studies in adult patients have been promising demonstrating a sensitivity of 100 percent for smear-positive patients and 71.7 percent for smear-negative, culture-positive patients. The system is currently under evaluation for the diagnosis of TB in children. Given the relatively good performance of GeneXpert in smear-negative case this may prove to be a useful tool for rapid diagnosis of TB in children.⁷

Other modifications of the PCR include strand displacement amplification (SDA), nucleic acid sequence based amplification (NASBA), branched DNA (b-DNA) and line probe assay (LiPA). One of the promising LiPA is GenoType MTBDRplus, (Hain Lifesciences, Nehren, Germany) wherein amplified DNA from regions of the genome involved INH and rifampicin resistance is hybridized onto a strip containing probes for the wild type (sensitive) as well as the most common drug resistance mutations.⁸ However, limited data exist on the performance of this test in smear-negative samples and these tests have not been specifically evaluated in childhood TB.

Indirect Approach in Diagnosis

Tuberculin Skin Test or Mantoux Test

It is one of the important tools used for supporting diagnosis of TB among children. 5 TU or lower dose is given intradermally and read after 48 to 72 hours (1 TU RT23 is the preferred dose). Induration ≥10 mm is considered positive for diagnostic purposes—suggestive of MTB infection, but is neither very specific or sensitive test. Ulceration, higher size of induration have little predictable relation with active disease. BCG vaccination can interfere with its interpretation.

Interferon γ Assays (IGRAs)

These tests use antigens which do not cross react with BCG and therefore these are more specific and sophisticated tests now available to detect TB infection. They provide the same information as TST but do not need a second patient visit for measurement and the results are available by 24 hours. Two commercially available IGRAs are ELISPOT-TB which uses *in vitro* stimulation of PBMCs with ESAT-6 and CFP-10 antigens and Quantiferon-Gold in tube test which uses *in vitro* stimulation of whole blood with these antigens, in addition to TB 7.7 antigen. However, none of these can detect active disease or make a distinction between infected, diseased and treated cases. These new tests thus offer limited incremental value compared to TST. The data on their role in immunocompromised (HIV), young children (<3 years) and malnourished children remain limited.⁹

The latest innovation has been combining the virtues of TST with IGRAs and preparing a *Lactococcus* fermented, recombinant skin test reagent which contains 1:1 wt/wt of rdESAT-6 and CFP-10. This investigational skin test reagent rdESAT-6 and CFP-10 appeared safe and non-sensitising in this first-in-man clinical trial in human volunteers and may form the future TST.¹⁰

Adenosine Deaminase

Adenosine deaminase is an enzyme required for the conversion of adenosine to inosine and is found in many
